The first is unnecessary radiological examinations. To avoid these, in a group of adults where there is a relatively low incidence of tuberculous infection negative Mantoux tests may be used to reduce the number of persons undergoing radiography as a part of their periodic examination. (Among medical students and hospital nurses judged by continental and American figures and by one set of English data—Edwards 1936—the incidence of negative reactors at the commencement of clinical training may be up to 20 per cent. or more.) In persons giving a negative response the test must of course be repeated at intervals so long as it remains negative.

Apart from the small economy obtained by Mantoux tests in such groups, it is usual for every individual to be radiographed at each routine examination even in the absence of symptoms since serial radiograms form the basis of the method. The presence or absence of symptoms is carefully noted but in the University College Hospital scheme at any rate physical examination is only made if symptoms or radiography suggests its advisability. This relegation of physical examination of the chest to an inferior position as a method of case-finding in tuberculosis may be objected to by some. It is however justified by results of clinical and radiological mass studies (see Reid 1934 Wingfield and MacPherson 1936 Trail 1936) while the impracticability in the present state of knowledge of sorting out adolescents for radiological examination by means of differences in general physical condition has also been pointed out (McKinlay and Watt 1934).

Anxiety state among examinees.—An objection usually raised to the principle in schemes of the type contemplated is that more harm will be done by producing neurophobia than good by detecting early disease (see for example Hutchinson 1934). At present this danger does not appear to have affected any established scheme to any serious extent the routine being accepted as of little mental consequence once the novelty has worn off. Since however every young adult population will contain many persons liable to develop anxiety about various diseases every effort should be made to implant health-consciousness rather than disease-consciousness. The eventual inclusion of periodic examination for early tuberculosis as part of larger schemes of health inspection should help towards this end. But the best argument against allowing the danger of creating tuberculo-phobia to hold up establishment of such schemes is that young adults more often than not already have an outstanding dread of tuberculosis—a dread founded on a sound knowledge of public health statistics. And the best weapon for removing this dread is to provide them with experience that the majority of their fellow workers who are found to have lesions return to their jobs after treatment. In any case the only alternative to schemes of this type—namely to emphasise early but vague symptoms—seems itself just a likely to produce neurophobia and with less return for the effort expended.

Stigma attached to tuberculosis.—Somewhat allied to the fear at present attached to tuberculosis is the associated social stigma.

This difficulty has to be faced in persuading members of schemes to undergo treatment when they do not feel particularly ill. If however the hopes placed in this method are fulfilled the gradual preponderance of mild sputum negative cases undergoing relatively short period of treatment should alter the popular and at present

substantially correct, picture of phthisis with its usual consequences

Moreover, the treatment of these slight cases may come to be simplified. Thus home supervision, with some degree of restricted life but without loss of work, has been used for some types "Ambulant" chrysotherapy has been suggested for certain early cases by Sayé (1934), while Diehl and Myers (1936) mention 16 students who have recently commenced pneumothorax treatment without loss of work. When sanatorium treatment is used, it may eventually be found practicable to arrange that sputum positive and asymptomatic cases are not sent to the same institution.

In association with these developments public instruction pointing out the importance of treatment of slight asymptomatic cases in preventing tuberculosis as it is usually known would be of value, while the sanatorium for such patients might appropriately be termed a preventorium. It is of interest that the present Sheffield tuberculosis service appears to be concentrating upon the hospitalisation and after care of the preclinical and minimal sputum negative case, regarding a sputum positive case as a comparatively late one, and claims by these measures to be reducing the stigma usually attached to the disease.

Classification—It may become advisable to classify the asymptomatic or preclinical case separately, as suggested by Opie (1935). In England this would necessitate subdivision of the *T B minus* class of Ministry of Health form 17/T (revised), the subgroups possibly to include such headings as slight or minimal, and asymptomatic progressive or preclinical. On the other hand, official recognition of insignificant or healing lesions not requiring treatment would be of little value. It should be emphasised that the gradual introduction of schemes of periodic examination in the country at large would have a marked effect upon the statistics of new cases, causing a gradual unnatural increase.

Difficulties in X ray interpretation—With a standard interval of a year one must expect to meet some cases that show extensive lesions and yet have had a negative previous examination (see Reid 1934), if only because some individuals will delay to report symptoms occurring during an intermediate period. Nevertheless, in a certain number of such cases the previous radiogram, on reinspection, may be found to show small shadows that had been regarded as insignificant, or had been missed altogether. A good quality of film, so far as possible comparable conditions, and a high degree of competence in interpretation are therefore essential, while even the smallest visible shadows could advantageously be recorded—for information only—at least until experience has been gained in the method.

When a particular shadow, ascribable to early tuberculosis, has been detected, difficulty may still arise as to its prognostic significance and as to any action required. It may be argued that many of the slight progressive lesions would have healed by themselves if left undiscovered, that others would do as well—even though by that time more extensive—if detected later on in the ordinary way, and that others will still progress unfavourably no matter what is done.

It may be stated, in reply, that the rationale of this method of diagnosis depends, so far as the individual patient is concerned, upon the hypothesis that, on the average, a slight and early case does better with than without treatment, and that with treatment it does better than does a later and more extensive case. The difficulty in interpreting a particular lesion, and of deciding any action required, can often be resolved after keeping the person under close observation. Intensive research, such as the

Prophit scheme, should add greatly to knowledge of the prognostic significance of these various early X ray lesions, but the results will not be available for some years, and delay in proceeding with trial routine schemes of periodic medical examination until then appears to be unjustifiable. In any case, even if they were assumed to be useless to the individual patient, such routine schemes would benefit the community by earlier removal of otherwise undetected sources of infection. Nevertheless, until further experience in interpretation has accumulated, we must face the occasional risk of unnecessary treatment as an alternative to postponing interference until too late. At the same time, this element of uncertainty makes it all the more necessary to see that treatment does not mean avoidable economic suffering.

Economic security of the examinee—If schemes of periodic examination are to be introduced on a large scale into industry, economic factors are likely to play a decisive part. I have already spoken of the temptation for a man to resume his occupation too soon and of the tendency to remain too long at work without seeking medical advice. But the financial difficulty is far greater when a man is advised to discontinue work and to undergo treatment at a time when he does not feel particularly ill. The assurance of economic security to the examinee would make this advice more acceptable, and would make him more likely to report suspicious symptoms arising in the interval between routine examinations—an integral part of the scheme.

Since the safety of the group of workers, as well as of the individual sufferer, must be considered, and at the same time the information obtained must be treated as confidential, the acceptability and success of a scheme would be best assured by providing economic security in some such way as the following. At the beginning information explaining its purpose might be circulated, with the assurance that under no circumstances will any worker suffer dismissal as a result of any discovery made under the scheme, and that where treatment is considered necessary he shall have the right to another opinion of his choice and shall receive, say, full wages (up to a maximum) for a limited period. The period might be chosen to cover the ordinary course of treatment and convalescence found after trial to be effective in favourable cases. The payments might be derived from a special sickness insurance fund.

Expenditure on schemes—The economic aspects of these schemes affect not only the individual but also the community, which ultimately bears the cost. Hence some estimate of expenditure must be attempted.

Probably the cheapest and most rapid radiographic method is that of the Powers X ray Tuberculosis Travelling Survey Service, a triumph of American mass production, which takes paper films at the rate of 150 an hour at an over all charge of about three shillings a head (Barnard 1934). The interpretation and clerical part of the examination are, of course not included in these figures. Presumably celluloid films, which are preferable, could be cheapened to satisfy a mass demand, but an apparatus for taking at high speed might be difficult to devise. The University College Hospital scheme absorbs 1 man hour per student per examination from the whole (medical, technical, and clerical) personnel and $\frac{1}{2}$ to $\frac{3}{4}$ hour from each student, but these times would undoubtedly be reduced as procedure became standardised.

In considering the return to be obtained for the expenditure in time and money, the number of cases likely to be found and the possible gain in the saving of life and man power, must be borne in mind. According to recent reports the incidence of clinical tuberculosis likely to be found in a survey of a young adult population in a large city of England or the United States is about 0.5 to 1 per

cent, while another 0.5 to 1 per cent may be found to have asymptomatic significant lesions potentially or actually progressive the figures being considerably higher where groups of contacts or persons in unusually poor environments are being examined (Barnard 1934, Downes 1934, Reid 1934, Fellows 1934, Opie 1935, Wingfield and MacPherson 1936). These figures must be taken as rough indications and the incidence of lesions would be expected to be somewhat smaller in subsequent examinations than in a first survey. Thus the incidence of (mainly young adult) applicants for employment at the Metropolitan Life Insurance Co. from 1927 to 1932 with significant active lesions requiring treatment was 0.4 per cent, while the annual incidence of new such cases among the actual employee population from 1930 to 1935 was about 0.2 per cent.

The average annual expenditure per head of the community on tuberculosis services is more than 2s. at the present time and the immediate increase in expenditure under this head due to schemes of periodic examinations were the whole population included would probably be at least double this amount annually for diagnosis alone. The expenditure on treatment per head of the community would also increase at first, since more cases of tuberculosis would be diagnosed and sent for treatment. But against this increase must be set the fact that much of the present expenditure goes to prolonged and unprofitable treatment and to the after-care of chronic cases with little prospect of resuming any useful occupation. If the proportion of cases diagnosed in a slight and favourable stage increases the expenditure per case should decline and this decline together with the hoped for reduction in new cases as the result of eradication of infective sources, will tend to offset the immediate increase in expenditure on treatment per head of the community.

The value to the community of the lives and health that might be saved by schemes of the type described, even if only assessed in terms of fecundity or of the monetary value of their potential work is however the most important consideration in estimating whether the increased expenditure entailed is justified. For the younger adult age-groups this value is enhanced by the notorious rapidly changing age-composition of the population towards a preponderance of older persons and by the recent decline in the birth-rate. (For calculation on an actuarial basis of the prospective money value of a man as a wage-earner at different ages, and according to the amount of his earnings see Dublin and Lotka 1930.)

PERIODIC MEDICAL EXAMINATION ON A LARGE SCALE

I have purposely emphasised the possible objections and difficulties. But since it is to be hoped that the method will in spite of them find increasing favour in this country it is well to conclude by indicating how such schemes might be introduced in the community at large.

It seems desirable at first to limit them to young adults aged 15-24 and to select groups that are easily accessible—more particularly those with a greater than average chance of developing progressive lesions. These categories will include university students and nurses, and persons attending diabetic and antenatal clinics. The next step might be to introduce schemes for young adults in State-controlled employment such as the civil service or Navy after which schemes might be developed among industrial groups, presumably under the control of the industrial medical or public health service.

At some point in their development these schemes would come into conflict with the diagnostic side both of the consultant and of the contacts service of the present tuberculosis dispensary system. It would be difficult even if it were desirable to avoid taking over the function of the former, but the future of the contact examination service is a more complex matter though obviously of great importance since the yield of cases is higher than in any other set of

persons. The points in which the present contact examination service differs from a fully developed scheme of periodic examination have already been described. There appear to be two alternatives for the future.

The first is that the present contact service be expanded and modified so as to work so far as possible on the model of the other fully developed schemes. The main object of expansion would be to render practicable the examination of a greater number of new adult contacts and to make their follow up more complete. This expansion even if limited to young adults, would have to be very considerable from the estimates given previously. A compromise might however be reached whereby adult contacts of all ages are radiographed once (to discover the primary infective source and any other cases) while further observation by periodic examination and serial radiography is limited to young adults in those families where the original case, or any other discovered at first examination is sputum positive. The main point in favour of retaining a contacts service in some form or other is the advantage of having one doctor in charge of a tuberculous person and his entire family for purposes of observation and social care.

The second alternative is to permit the functions of the present contact examination service to be taken over by the fully developed schemes of periodic examination (which of course include non contacts as well as home contacts). Certainly the dual purpose of the latter—to help prevent disabling pulmonary tuberculosis and to help prevent spread of infection to others—seems to cover the diagnostic functions of any special contacts service. And it is possible that selection of a group of young adults on an industrial or study basis rather than on a family basis might do more to achieve this dual purpose because of the greater accessibility of the examinees while the determination of an individual's first examination under a scheme by his age rather than by the discovery of a clinical case of tuberculosis in his proximity might also be an advantage. The industrial or other fully developed schemes would allow the close observation of persons who have had pleurisy the full importance of which as a precursor of progressive pulmonary lesions is becoming increasingly realised (see Traill 1937). Finally the industrial or other schemes could form part of a comprehensive health service that would include the detection of pulmonary tuberculosis as merely one of its important functions.

Conclusions Regarding Early Diagnosis

Earlier diagnosis and treatment of progressive pulmonary tuberculosis among adults should benefit the community by helping to prevent the more serious forms of the disease, to restore more persons to health and work and to eradicate sources of infection. For achieving early diagnosis in the past we have tended to concentrate upon the early clinical cases—i.e. the patient who already has symptoms or physical signs. In the future we must concentrate upon the preclinical case. In the past we have for the most part attempted to recognise the presence of progressive lesion soon after symptoms have developed by a single examination at the request of the individual when he feels ill. In the future we must try as far as possible to discover these lesions before the onset of definite symptoms by the routine periodic examination of selected groups of individuals, particularly young adults, supposedly in health, serial radiograms and (especially where a low tuberculous

infection incidence prevails) Mantoux tests would be the basis of such examinations

* * *

With its sensitivity to social conditions, its chronic course, its infectiousness, and its possible detection before signs and symptoms develop, and with the benefits attainable from early treatment, pulmonary tuberculosis has offered and still offers remarkable opportunities for the practice of preventive medicine. And the four measures particularly emphasised in these lectures—social measures applicable to the community at large, social measures applicable to the individual sufferer and his family, protection of members of the community from infectious disease, and the detection of the first signs of deviation from health—reflect the varied aspects of preventive medical practice in general. Furthermore, the changes envisaged in applying these four measures to the particular disease tuberculosis coincide with a general movement of the profession towards regarding maintenance of health as its primary goal, and towards a greater interest in those social conditions often forming the background of illness. The measures used in the fight against tuberculosis can form the spearhead of this movement.

I wish to record my deep gratitude to Prof G Payling Wright for the advice given throughout the preparation of these lectures. I wish also to thank Dr G W Pickering for suggestions towards improvement of the text, Dr A J Morland and Miss H M Matheson, of Holborn Tuberculosis Dispensary, and Dr C H C Toussaint and Miss O J Pike of Bermondsey Dispensary, for supplying certain data, and Dr J E Chapman, Dr T O Garland, and Dr D H Mills for help on special points.

LANCASHIRE MENTAL HOSPITALS—The Minister of Health has sanctioned the borrowing of £488,666 by the Lancashire Mental Hospitals Board for works in connexion with the extension of the Brockhall Certified Institution for mental defectives to provide accommodation for 1326 additional patients. This will bring the total accommodation of the institution up to 2098. The additional accommodation to be provided includes a hospital, school, work rooms, recreation hall, staff cottages and administrative buildings.

SEAMEN'S HOSPITAL SOCIETY—The Earl of Athlone, presiding at the annual meeting of the court of governors of this society on April 21st, said that at the new Albert Dock Hospital a model fracture clinic is being built through Lord Nuffield's generosity where after discharge from the wards, patients will be retained under observation and treatment in the rehabilitation centre. There will also be a dining room where men who only receive a maximum of 30s a week as compensation pay will receive proper nourishment. Only £9500 is now required to complete the appeal made by the Albert Dock Hospital rebuilding fund for £50,000.

INSULIN SHOCK TREATMENT OF SCHIZOPHRENIA

By G W B JAMES M.C. M.D. Lond.

PHYSICIAN FOR MENTAL DISEASES TO ST. MART'S HOSPITAL,
LONDON AND MOORCROFT HOUSE, HILLINGDON LECTURER
IN MENTAL DISEASES AT ST. MART'S HOSPITAL
MEDICAL SCHOOL

RUDOLF FREUDENBERG M.D. Freiburg

ADJUNCT PHYSICIAN TO MOORCROFT HOUSE HILLINGDON AND

A TANDY CANNON L.R.C.P. Irel.

ASSISTANT PHYSICIAN MOORCROFT HOUSE, HILLINGDON

GROWING interest is being shown in the insulin shock treatment of schizophrenia introduced by M Sakel in 1933 at the Pötschl Clinic Vienna. By the courtesy of Prof O Pötschl we were enabled to study the method in Vienna and formed the opinion that it may prove to be an important therapeutic contribution to the attack on a disease which has hitherto defeated most curative efforts by its chronic and progressive course. As a result we have used the insulin shock therapy at Moorcroft House, Hillingdon since the beginning of the present year. To discuss results would be premature in view of our brief experience; it may be said in general that they are encouraging.

References in British journals to this form of treatment are at present limited. Apart from the well known study by I G H. Wilson (1936) there has been a brief note by D K Henderson (1936) in the report of the Edinburgh Royal Hospital on the cases treated there by P Strocker and recent articles by L W Russell (1937) and E H Larkin (1937). The latter are of special interest in that they report the use of the treatment in two English hospitals and set out the results obtained in a small series of cases.

Some definition of terms commonly confused may be useful at the outset. It is essential to distinguish between shock and coma sometimes used synonymously. The term shock should be confined to the period of time between the initial symptoms of hypoglycemia and their interruption by the administration of glucose. The term coma on the other hand, should be limited to the stage of hypoglycemia during which consciousness is lost; the patient being insensible to stimuli such as shouting his name or touching his body. We speak of deep coma when hypotonus appears, the corneal and plantar reflexes being absent. Deep coma should never be permitted to last longer than 1½ hours.

We attach great importance to certain details in which our technique differs from that outlined by Russell and by Larkin. For example Russell states that he leaves the patient in coma for 2-2½ hours daily but fails to say by what standards the depth of coma is measured. If the patient is left more than 1½ hours in deep coma there is serious risk that restoration may be difficult. Larkin avoids the occurrence of epileptiform fits by premedication with Prominal. Our experience confirms the generally accepted view that fits are useful therapeutic accidents. In selected catatonic cases we have therefore induced occasional epileptiform seizures by the intravenous use of Cardiazol insulin being omitted on these days, thus combining the methods of I Meduna (1937) and Sakel. These Cardiazol seizures lasting a few seconds require no remedial interference but fits occurring during hypoglycemia must be interrupted

forthwith on account of the danger that status epilepticus may develop.

More importance should be attached to constant medical attendance on patients in hypoglycemia. Alarming emergencies may arise sudden in onset and serious in their results. Hypoglycemic coma may be compared with anaesthesia and the anaesthetist never leaves his patient. A doctor should remain in the insulin department from the time of the injection until the last patient is awake. When six or more patients are undergoing treatment a second doctor should be quickly available during the critical period of hypoglycemia (in our case 10 A.M. to noon) as it has happened that we had to deal with two or more emergencies simultaneously. Care must be exercised to ensure that the nursing staff can obtain a doctor at short notice for the rest of the day and following night.

If wide departures are made from the established principles of the treatment as evolved by its originator serious risk to life will ensue and the method may thereby be brought into disrepute. These considerations must serve as our excuse for recapitulating in detail the technique used in Vienna. Munzinger and Otwork carefully summarised by E P Frostig in a lecture given to the Arbeitsgemeinschaft für Psychiatrie und Pathophysiologie Vienna in 1936 and as far as we know unpublished. We include a description of the major manifestations to be expected during the shock period and their management with the object of obtaining maximum therapeutic results with a minimum of risk.

THE SELECTION OF MATERIAL

The criteria of the diagnosis of schizophrenia is one of the first difficulties. The standards are subject to slight variations in different countries and even in different schools in the same country. All workers should follow a definite plan for arriving at the diagnosis and report the data on which that diagnosis rests. Further the different classes into which workers divide schizophrenia should be clearly defined and described as it would seem that insulin therapy produces different results in the separate clinical types of the disease. Our own diagnostic requirements roughly follow the classical description of dementia praecox and paraphrenia by Kraepelin and therefore include patients that some writers would distinguish from schizophrenia. In recording histories it is of the utmost importance to differentiate between the more chronic and progressive cases and those with acute onset and a tendency to show remissions; this differentiation will be found essential when a final assessment of the worth of the method comes to be made. We would stress the importance of classifying the cases according to the duration of schizophrenic symptoms: they are usually grouped under headings which distinguish the length of the illness as up to six months up to one year up to eighteen months and over eighteen months.

PHYSICAL EXAMINATION OF THE PATIENT

A detailed and orderly physical examination is essential. This is especially necessary if advanced cases are to be treated. Contra indications to insulin therapy are not yet clearly defined and further accurate information on this subject is needed.

The rule at Moorcroft House is that when routine examination reveals any suspicion of organic disease—especially cardiovascular or hepatic disease—the treatment is postponed or abandoned. We have learned to pay particular attention to the lean asthenic type of individual with cold extremities

and low blood pressure. Our experience teaches that such types are highly sensitive to insulin, often produce severe hypoglycæmic manifestations, and prove difficult to arouse from coma after the administration of glucose. Such difficulties appear to us less common in the athletic and pyknic physical types. In asthenic types insulin may more often produce toxic hypoglycæmic reactions and after effects, which include vomiting, diarrhoea, tachycardia, and pyrexia. When such manifestations occur, treatment (after a short rest) is carried on with much reduced doses. The patient may then acquire a higher level of resistance, described by E. Küppers (1937) as "adaptation." In the experience of one of us (Freudenberg 1936), this adaptation is assisted by giving intramuscular injections of vitamin B, together with an extract of suprarenal cortex every evening until adaptation is established. In a few patients very resistant to insulin premedication with alkalis—e.g., sod. bicarb—orally or intravenously has been found to increase sensitivity (R. F.)

BRAND OF INSULIN

All the experience gained of insulin shock therapy has been obtained by the use of pancreatic extracts. These extracts are standardised experimentally by their effects on the blood sugar of rabbits. The mechanism of the effects of high doses of insulin continued over a long period, as in insulin shock therapy, has not yet received sufficient experimental investigation, these effects having been studied chiefly by clinical observations recently summarised by K. Th. Dussik and R. Freudenberg in a lecture given to the Arbeitsgemeinschaft für Psychiatrie und Pathophysiologie, printed by Ars medica Verlag, Vienna, 1937.

There seem to be small differences in the effects produced by different trade preparations of insulin. For this reason the commercial preparations used should always be mentioned in records of cases. We have used the Wellcome brand of pure crystalline insulin. Our experience confirms the view of Müller (1936) who lays stress on the apparent increase in sensitivity to insulin which occurs in many patients during treatment. We believe this change in sensitivity to be of the utmost importance, and it is our rule to attempt to diminish the amount of insulin once the coma dose has been reached. Other patients develop increased resistance to insulin in the course of treatment. It is of interest that increased sensitivity may change to a high resistance to insulin in the same patient. These facts have not yet been satisfactorily explained. During our fifteen weeks' experience crystalline insulin has not produced an urticarial rash in any of our cases. The "Wellcome" brand has the great advantage of being prepared in three strengths, 80, 40, and 20 units per c.c.m., thus saving patients on large doses much discomfort.

PHASES OF THE TREATMENT

Phase I—The usual practice is to begin the treatment with a subcutaneous injection of 20 units of insulin (or less in the case of debilitated patients) given at 7 A.M., the patient fasting from 7.30 P.M. the night before. This dose is increased daily by 5 to 10 units until the initial coma dose (15–300 units) has been reached. In two of our cases 30 units produced severe epileptiform convulsions less than one hour after injection, in one of these coma is now obtained with 15 units. This patient was of the asthenic type. The duration of phase I depends on the sensitivity of the patient, the amount by which the dose is increased, and probably also on factors which are

at present unknown. The physical and mental signs and symptoms in phase I are here briefly described as far as possible in the order in which they appear. No hard and fast rule can be laid down either as to the time or order in which they arise. Indeed, some patients seem to present very few signs and symptoms in phase I, and the manifestations may vary from day to day in the same patient.

During the first hour signs and symptoms are mostly absent. Flushing of the face is usually the first noticeable change, and may be followed by a mild euphoria, accompanied by giggling and often a feeling of well being and strength. Commonly associated with the euphoria is a period of lucidity and insight which will be referred to below. The patient often complains of hunger. Sweating may occur with the flushing, but is more marked later when the flush has given way to pallor. Somnolence follows, often after a short spell of restless tossing in the bed. The euphoric period may develop into almost any type of excitement from singing, whistling, and obscene remarks, to a wild psycho-motor restlessness, with constant incoördinated movements, from which injury may result unless padding of the bedstead is adequate. There is usually a preliminary rise in the pulse rate, and slowing in the later stages. Myoclonic twitches may appear in the third or fourth hour, when the patient is gradually losing consciousness, and may develop into an epileptiform attack.

Interruption in this phase is carried out by making the patient drink sugared tea (7 oz. of sugar in 500 c.c.m.).

Phase II—This is the phase which is ushered in by the establishment of the initial coma, afterwards repeated daily during this phase of the treatment. In coma the patient is unconscious and incapable of being roused, as it progresses salivation becomes profuse, and extensor plantar responses, often bilateral and spontaneous, appear. Next hyper-tonus, usually in flexion, is seen but this should disappear and give place to hypotonus.

From the clinical point of view the coma now enters on a stage requiring careful observation. With hypotonus and flaccidity of the muscular system generally, the reflexes disappear. There is no response to the plantar reflex, the corneal reflex is absent, the deep and superficial reflexes cannot be obtained. Eventually, if the coma is allowed to proceed, hypertonus may reappear. The upper limbs are rigidly extended in pronation, the lower limbs become rigid in extension, opisthotonus may occur and the patient resembles the decerebrate animal. With the early hypertonus and myoclonic twitches the pupils tend to be dilated. When hypotonus and flaccidity occur and the corneal and other reflexes fail, the pupils are contracted. Finally, in the stage at which hypertonus reappears, the pupils again dilate and may fail to react to light. In this condition, referred to above as resembling the decerebrate animal, interruption becomes an immediate necessity.

Dosage should be arranged so that coma does not begin until the third hour following the insulin injection. If coma commences prematurely it is a sign that the dose is too big.

A word of caution as to the management of all cases during the hypoglycæmic period may be added here. Patients should be left as quiet as possible. Movements or struggling will produce compensatory secretion of adrenaline, resulting in a lessening of the depth of coma.

Phase III—This term was used by Sakel to denote periods of rest. It is still used in this sense and now means the weekly day of freedom (Sundays), and the compulsory rests after the patient has suffered from "emergencies" (see below), or after effects of treatment. A day or more of rest should also follow diarrhoea and pyrexia.

Phase IV—This phase (withdrawal of the therapy) begins when no further clinical improvement can be obtained and in any case after about three months of treatment. The dose of insulin is reduced to roughly one-third or less of the coma dose and interruption is carried out about 2 hours after the injection. This process occupies from 4 to 8 days.

INTERRUPTION

In phase II interruption is normally carried out by the nasal tube. We believe the tube should be passed only when the patient is in coma. Gastric secretion usually increased in quantity is withdrawn and tested by litmus paper so that there can be no question that the tube has arrived at its proper destination. A precautionary passing of the tube at an early stage of coma is justified when signs such as severe myoclonic twitchings suggest that a state of emergency is imminent. If such precautionary insertion of the tube has been carried out and a period of time has elapsed before actual interruption the gastric juice is again tested. A funnel and tube with a glass connexion enables dilute sugared tea (7 oz. in 500 c.c.m.) to be run into the stomach. When a patient is known to have a tendency to vomit 2 minims of 1 : 1000 solution of atropine sulphate are introduced through the tube before the feed. During the whole of this operation the tube is held in position by doctor or nurse. For patients refusing meals this opportunity is used to administer a good feed containing the same amount of sugar with milk cream and three eggs. After the introduction of the feed the nasal tube is removed immediately. Our experience supports the view that patients are adversely affected by waking to find the nasal tube in position and we consider that to leave the tube in situ until the patient awakes as advised by Larkin is undesirable. Waking should take place within 20 to 30 minutes and the patient is then given cake or biscuits and milk to drink. During coma the body temperature falls to a very low level often under 95° F. After interruption patients appear cold with shivering and goose flesh and it is our practice to have hot-water bottles ready to apply in every case.

The daily length of the coma must be extended gradually and never continued beyond a period (discovered by trial) that allows the patient to awake easily and without after effects. There is an optimum duration of coma for each patient which is often less than 1½ hours.

After interruption patients rest in bed for about half an hour care being taken to change the clothing which is generally soaked in perspiration. Patients take an ordinary lunch and someone must see that sufficient food is taken at all subsequent meals or late hypoglycemia symptoms may occur. It is our practice to record the food consumed during the day, a task entrusted to one of the nurses.

AFTER EFFECTS

Interference must be made to after effects rare if proper precautions are observed. Among them is vomiting with loss of the glucose feed and resulting repetition of any of the hypoglycemia signs including coma and fits. Intravenous glucose may be required when this happens but if the patient is sufficiently awake and the manifestations of hypoglycemia are slight carbohydrate food may be given by the mouth. A less frequent after effect is the progressive deepening of the coma subsequent to the administration of glucose. When this phenomenon is observed intravenous interruption is required.

General Indications for Interruption

Hypoglycemia must always be interrupted—

- 1 By the end of the fifth hour from the time of the injection—e.g. by noon if beginning at 7 A.M.
- 2 Whenever gross disturbances or variations of the pulse occur—e.g. irregularities or rates of over 120 or less than 40.
- 3 If hyperextension of the limbs with pronation of the upper limbs is persistent.
- 4 In the presence of stridor with cyanosis and movement of the accessory muscles of respiration.
- 5 When hunger excitement occurs (Sakel 1935). This is to be distinguished from the customary requests for food, and consists of wild excitement and a fierce shouted insistence on an immediate meal.

Interruption should take place at whatever stage of the hypoglycemia these general indications appear. Sometimes the patient is able to drink his sugared tea but usually the nasal tube is required.

INDICATIONS FOR INTRAVENOUS INTERRUPTION EMERGENCIES

The following emergencies are indications for intravenous interruption—

- 1 Respiratory embarrassments which include the sudden cessation of respiration and laryngeal spasm.
- 2 The premature incidence of coma. A premature coma tends to deepen with alarming rapidity. This phenomenon results from an undue increase in the initial coma dose or in a specially sensitive patient.
- 3 Obvious cyanosis of the mucous membranes with a weak and rapid pulse.
- 4 Epileptiform fits. These attacks may occur at any time in the hypoglycemic period or after interruption. Fits after interruption usually develop within 40 to 60 minutes. They may occur rarely at a much later period should hypoglycemia for any reason return. In addition to the intravenous glucose the nasal tube should be passed and a feed inserted into the stomach, thus providing a carbohydrate depot on which the patient can draw. In the epileptiform attack, the usual precautions against tongue biting are taken.
- 5 Cardiovascular collapse. In this sudden emergency subcutaneous injection of adrenaline (1 c.c.m. of 1 : 1000 solution) is the best initial step. Intravenous therapy may be rendered impossible by the collapsed condition of the veins in which case the pharyngeal strand proceeds to give an intraventricular injection of 2 to 4 c.c.m. of 33 per cent glucose solution. If adrenaline has not already been given subcutaneously or intraventricularly it may be added to the intraventricular injection.
- 6 Vomiting.
- 7 A state of wild psychomotor excitement with flushed face and dilated pupils. This condition is sometimes seen after interruption by nasal tube and in such cases intravenous glucose must be given. If the excitement continues lumbar puncture will sometimes be necessary. I amidehyde or sodium hyaluronate by the rectum are useful.

CERTAIN POINTS OF TECHNIQUE

Lumbar puncture is essential when the patient fails to awake after intravenous interruption. If this condition becomes more advisable and can be done 300 c.c.m. of blood can be withdrawn.

A 33 per cent. solution of glucose is used for intravenous interruption the injection being from 60 to 120 c.c.m. being sufficient to awake in most cases. We use 50 c.c.m. syringes which are refilled while the patient remains in position.

There is one negative measure which is never found very useful in certain emergencies—namely the use of mixed carbon dioxide (5 per cent.) in a closed space. Administration of this gas is especially useful in cases of cyanosis who fail to awake after intravenous interruption. It has also relieved

We have applied the suggestion of Sakel (1936) that paranoid cases be treated with deep coma. He advocates that in treating catatonic stupor interruption should be effected while the patient is in a euphoric or excited condition. This often puts an end to the stupor, exposing a loose system of paranoid ideas. Subsequent treatment should then be directed towards obtaining deep coma. On the other hand, catatonic excitement should be interrupted during the period of quiet somnolence before the onset of coma, carefully avoiding interruption during excitement. When the patient has become sufficiently quiet the treatment is continued with daily coma.

We never use adrenaline to secure interruption, its use for this purpose having been abandoned in Vienna. We reserve it for cardiovascular collapse and laryngeal spasm.

PSYCHOLOGICAL SYMPTOMS AND THERAPEUTIC MEASURES

We have already stated that before coma appears euphoria is common, with some degree of lucidity and insight. This is an opportunity for the physician to re-establish contact with inaccessible patients. A word of warning is here necessary. Throughout the treatment until comatose, patients are extremely sensitive and exhibit a pronounced hyperacusis. Caution must be exercised as to what is said in the neighbourhood of the patient, even in a whisper. An unwise chance remark may act as a serious psychic trauma. It is best to leave the patient alone while he is waking from coma and, in the early days of the treatment, to avoid any discussion with him concerning his illness. Such discussion has in our experience resulted in relapse in an otherwise improved patient. For this reason the visits of relatives are a potential source of danger.

The phenomenon of "reactivated psychosis" is described by Sakel (1935) as a reproduction of psychotic symptoms during the hypoglycæmic period, the patient being normal during the rest of the day. This phenomenon has frequently been observed by us, and seems to be explained as a combination of the "insulin psychosis" observed in mentally normal diabetics, and the actual schizophrenic condition for which the patient is being treated. Sakel advises that phase II should be continued until the "reactivated psychosis" disappears. There does not seem to be general agreement on this point, and our experience is still too limited to enable us to form an opinion. All agree that the daily hypoglycæmia should never be interrupted during "reactivation".

The care of the patient after interruption is important. So far as is feasible we try to ensure that some definite occupation is provided for the afternoon and evening. Patients leaving the grounds should be accompanied by a nurse or responsible relative and chocolate should be carried as a convenient form of sugar in case of any return of hypoglycæmic symptoms. This has actually occurred to one of our patients during a walk. Night nurses must be familiar with the signs indicating hypoglycæmia, and must be instructed to pay frequent visits during the night to patients undergoing treatment.

CLASSIFICATION OF RESULTS

We are often asked as to the mortality to be expected among patients treated with insulin shock therapy. The most recent figure from a series of 400 cases (Küppers 1937) is 1.5 per cent. It must not be forgotten that the 400 cases collected by Küppers contain those treated in the early days when mortality

was higher from inexperience and faulty technique. We believe that the death rate will always prove to be in inverse relationship to the care with which a proved method of technique is adopted and applied.

We would strongly recommend the adoption of some standard method recording results. We suggest the four categories established by Müller (1936).

1 *Complete remission*—This category represents complete disappearance of schizophrenic symptoms, with normal affective relationship, full insight, and ability to return to the normal sphere of work.

2 *Incomplete remission*—This category includes patients who are able to work but with persistence of any one of the psychic symptoms described under 1.

3 *Partial remission*—Patients in this category are able to resume work, symptoms remain without interfering with their daily life.

4 *Unimproved*, and requiring hospital care.

CONCLUSION

It seems likely that this method will be given an extensive trial in this country, and it is clearly of the utmost importance that fresh workers, or those already engaged on this work, should make a serious attempt to coördinate and standardise not only the technical side of a difficult and laborious procedure but also the criteria of diagnosis by which cases are selected, and the classification of results. It is hardly necessary to enlarge on the advantages gained from such standardisation. First, the undoubted dangers of the procedure will be minimised by the adoption of the proved technique. This is not meant to imply that no modifications are possible, they are bound to be tried. But in applying a method of treatment that is not without danger to life, it seems to us wise to follow closely a technical procedure already fully tested in Vienna, Munsingen, and elsewhere. Secondly, if it is possible to arrive at agreement on the criteria of diagnosis, the cases selected for treatment will command a general acceptance as properly belonging to the schizophrenic group of mental disorders. Thirdly, agreement on classification of results will enable a quicker judgment to be made of the real value of the new method.

TREATMENT OF URINARY INFECTIONS WITH CALCIUM MANDELATE

By EDGAR SCHNOHR, M.D.

(From the Surgical Department at the Sundby Hospital, Copenhagen)

MANDELIC acid has been widely used in the treatment of urinary infections since Rosenheim introduced it in 1935, and the results published have all been excellent.

I have treated 30 patients with sodium mandelate and ammonium chloride as originally advised by Rosenheim, and found that in 23 the urine was sterile after 4-30 days, although several were severely ill, some with stones and urinary stasis. The only disadvantage of the treatment is that mandelic acid

has a very disagreeable taste and not infrequently causes nausea and vomiting. For some patients the dyspeptic discomfort was enhanced by the ammonium chloride and occasionally the treatment had to be given up. This led me to try the calcium salt of mandelic acid which unlike the sodium and ammonium salts is quite tasteless. The preparation used* has the following constituents—

Calcium mandelate	72.25
Cocoa powder	7.50
Saccharum purificatum	20.00
Saccharinum solubile	0.02

It is in granular form and one level dessertspoonful contains 2 grammes of mandelic acid. In the stomach calcium mandelate is broken down to mandelic acid and calcium chloride most of which is converted into non absorbable calcium salts in the intestines. This gives a surplus of mandelic acid. Since a part of the administered calcium is absorbed together with the mandelic acid, the calcium mandelate will have a less pronounced acidifying effect than ammonium mandelate the all ammonia of which is converted into urea. I have found however that with calcium mandelate it is possible to obtain a sufficiently acid urine. The values of pH obtained have corresponded exactly with those following administration of sodium mandelate with ammonium chloride or of ammonium mandelate.

The results of treatment in 8 cases are summarised in the accompanying Table.

Result of Treatment with Calcium Mandelate

No. of Case	Sex and age	Duration of infection	Diagnosis	Days before urine became sterile	Lowest pH during treatment
1	F 41	2 cols 5 yrs	Pyelitis	4	1.9
2	F 29	2 cols 3 yrs	"	4	4.8
3	F 6	2 cols 1	Pyelitis, polypus vesicae, cholelithiasis, cholecystitis	0	4.8
4	F 57	2 cols 4 yrs.	Pyelitis, uretero lithiasis	8	5.1
5	F 51	Hæmaturia 1 mth.	Cystitis; pregnancy	3	5.5
6	F 35	2 cols 1	Pyelitis, chronic salpingitis, cystitis, degenerated ovaries	6	5.0
7	F 33	2 cols 8 days	Pyelitis, nephrolithiasis, dilatation of pelvis	Crystal clear within 10 days	5.3
8	M 51	2 cols 3 yrs	Pyelitis, nephrolithiasis, dilated calyces and ureter stone in the lower urethral stricture	After 10 days no growth of <i>B. coli</i> continued growth of <i>proteus</i>	5.5

Case 5 was given 6 grammes of mandelic acid daily for the other 12 g.

With all the reservation necessary when comparing groups of 30 and 8 patients I must nevertheless express my opinion that the infection of the urinary passages was if anything more serious in the 8 patients who received calcium mandelate than it was in those who received sodium or ammonium mandelate. And the therapeutic result was at least equally

satisfactory. It is especially worth noticing that the urine became sterile in Case 4, in which pyelitis was complicated by the presence of an ureterolith and dilatation of the urinary passage. The same thing happened in Case 7 where there was nephrotosis dilatation of the pelvis, and a kink in the ureter. In Case 3 where pyelitis was complicated by polyp in the bladder a month's treatment with sodium mandelate plus ammonium chloride had no effect on the infection yet after giving calcium mandelate for nine days the urine was sterile. It is hard to see how the calcium salt could be more effective than sodium mandelate plus ammonium chloride when—as in this patient—the acidity of the urine is identical and it is easiest to assume that continued treatment with sodium mandelate would have given the same result, though sterility of the urine is seldom so long delayed. If there is a therapeutic difference, it is presumably attributable to some action by the calcium ion itself on the infection.

Regarding the question whether it is justifiable to give mandelic acid in cases of renal insufficiency I would point out that three weeks previously this patient had had serious renal insufficiency with temporary anuria and greatly increased blood urea—a condition I suppose of azotémie par manque de sel. The mandelic acid did not in any respect impair the function of the kidney.

Of the two patients whose urine did not become sterile the first (No 7) had bilateral nephropoiesis, dilatation of the pelvis and a kink in the ureter. On the tenth day (when this report was brought to a close) the urine was as clear as crystal but still gave a scanty growth of *B. coli*. In Case 6 there was associated infection by *coli* and *proteus* also there was a stricture of the urethra retention of urine dilatation of the calyces and the pelvis on one side and a concretion in the pelvis—conditions which make it unlikely that cure will be attained by medical means. The *proteus* infection did not respond to the treatment but on the other hand the *coli* disappeared within ten days.

All 8 patients who were given calcium mandelate agreed that it had no taste and in 5 of them it caused no dyspeptic symptoms whatsoever. Among these patients was No 3 who had previously had sodium mandelate and ammonium chloride which made her vomit.

Of the 3 patients who had nausea after calcium mandelate No 6 had no dyspepsia when she took the medicine between meals and washed it down with water. No 7 was only nauseated for the first two days and No 8 not until six days had passed. In no case was it necessary to stop the treatment because of dyspepsia. Thus there can scarcely be any doubt that calcium mandelate has a great advantage over treatment with sodium mandelate and ammonium chloride.

SUMMARY

A new preparation in which mandelic acid is presented as the calcium salt has been tried in the treatment of urinary infection. It is tasteless seldom causes dyspeptic symptoms and gives a sufficiently acid urine.

Treatment of 8 patients with this preparation gave the same good results as treatment with other preparations of mandelic acid.

I am indebted to Prof. Svend Hansen, chief of the surgical department of the Sundt Hospital, for permission to report these cases.

* It was placed at my disposal by the Ferro-an Co., Copenhagen and is sold by them under the name of Camydal and is obtained in Great Britain from H. H. Napp Ltd., London.

CORNEAL GRAFTING (KERATOPLASTY)

REPORT OF A CASE

By T H SPENCER TIZZARD, M B Glasg, D O M S

HON SURGEON TO THE EYE INFIRMARY, BATH

CORNEAL grafting was first successfully practised as long ago as 1888 by von Hippel. His method was to use a mechanical trephine, which is, however, a difficult instrument to control, and liable to inflict severe damage. The same method has been used by Elschnig. Castroviejo (1934) employs a twin bladed knife which cuts a rectangular graft, thus he retains in position by means of a conjunctival flap. Tudor Thomas (1930, 1931) obtains his graft by using a circular trephine of just over 4 mm in diameter. In his method the cornea is cut with the trephine as far as the deeper layers, and he then uses a pair of finely curved bevelled scissors to cut the remaining portion. This shelving process prevents the cornea from becoming dislodged and slipping into the anterior chamber. The recipient's eye is trephined in the same way, but the instrument is of a slightly larger diameter. Thus the graft can be more easily slipped into the bed. It is retained in position by an ingenious method of cross stitching.

To retain the graft in position Castroviejo draws the conjunctival flaps together over the graft by undermining the conjunctiva from the limbus backwards above and below. Rycroft (1935, 1936) employs a complete conjunctival flap, which is drawn like a tent over the entire cornea and the graft, and retained in position by a purse string suture.

INDICATIONS

Cases of grafting are done in which opacification of the cornea is due to interstitial keratitis, healed ulcers, and chemical burns. In interstitial keratitis the eye should have been quiet for at least twelve months.

Cultures should be taken from the conjunctival sac of the donor and the recipient. The operation is contra indicated if any pathogenic micro-organisms are grown during forty eight hours' incubation. Tension should be within normal limits. There should be accurate projection of light and there must be no active inflammation.

CASE REPORT

The following case is that of a young man of 21 who two years previously had very severe interstitial keratitis involving both eyes.

The patient first attended the Eye Infirmary, Bath, in the summer of 1935. Both corneas were opaque. In the right eye there was perception of light, in the left of hand movements. The pupils were fully active, but it was not possible, owing to the diffuse corneal opacities to view even a portion of the fundi through the dilated pupil. It was noted that there was an anterior capsular cataract in the left eye, but owing to the density of the corneal opacities in the right eye I was unable to see whether there was a similar cataract in this eye. He had had 18 months previously a full course of Novarsenobillon, extending over six months at another eye hospital. As interstitial keratitis can recur, a very small peripheral iridectomy was performed on the right eye, the object being to see how it reacted. The eye remained perfectly quiet after the operation. Since vision in the right eye was less than in the left vision being so poor that it was useless as an organ of sight, I decided to do the corneal graft if possible on this eye. During the time he was in the infirmary in 1935 he was given mercury and iodide.

It was not until the summer of 1936 that a suitable eye was found from which to take a graft. The cornea for grafting purposes should be quite transparent and clear and of normal thickness. I considered that a cornea taken from a glaucomatous blind eye would be unsuitable, as it would have been subject at some time to abnormal stresses. The eye that became available was taken from a man who was hit with a piece of steel, disorganising the interior of the eye, but leaving the cornea in part uninjured.

OPERATION

The evening before operation the palpebral conjunctiva was painted with 2 per cent silver nitrate, and afterwards irrigated with an alkaline lotion. Gut eserin $\frac{1}{2}$ per cent was instilled into the right eye. The morning of the operation gut eserin $\frac{1}{2}$ per cent was again instilled into the right eye.

The recipient's eye was anaesthetised with Pantocain, a derivative of novocain that has no deleterious effect

Right eye before and three months after, operation

upon the corneal epithelium and no effect on the pupil or intraocular pressure. The 7th cranial nerve was blocked with Novutox at the site where its branch crossed the neck of the condyle of the mandible. Complete paralysis of the orbicularis oculi was secured with an injection of 2 cc cm.

Preparation of the site in the recipient's eye was first begun. The conjunctiva was dissected from the limbus in its whole circumference, and the conjunctiva was undermined and freed from the underlying tissue, so that it could be drawn over the cornea by a purse string suture. Bleeding points were few and were easily controlled by adrenaline, and there was no need to use a cautery. The site of the graft was delineated by placing a trephine (4.63 mm) over the centre of the cornea and cutting through the epithelium. The trephine was removed and a drop of sterile fluorescein was placed on the cornea. This outlined the graft. When the section had involved half the thickness the trephine was slightly tilted to one side so that the cutting edge was directed obliquely through the deeper layers of the cornea. The anterior chamber was thus entered. The trephine was removed and the section was completed by dividing the remainder of the cornea with a pair of scissors whose cutting edges were bevelled.

The corneal graft from the donor's eye was removed in the same way, but with a trephine of 4.5 mm so that the piece of cornea could easily fit into the bed prepared. The corneal graft was removed by sliding a retractor beneath it and placing it in a watch glass filled with sterile normal saline and little above body temperature.

The bed for the graft having been prepared, very little time was lost between removing the graft from the donor and placing it in its new bed. The conjunctiva was now drawn completely over the graft and the cornea the former being kept in position by an oiled retractor which was placed through a small hole underneath the "tent" so to speak, and held gently on the surface of the cornea, while the purse strings were drawn tightly over it. One now felt that the graft was really in position and had not been dislodged when drawing the conjunctiva over it. Atropine oil was instilled and both eyes bandaged firmly.

PROGRESS

On the fourth day the bandages were removed and one drop of atropine oil was instilled into the operated eye. The graft at this time could not be seen as it was still completely covered with conjunctiva. The patient complained of no pain or discomfort. The eyes were again firmly bandaged. On the sixth day the bandages

were again removed and the graft was seen in position and it was quite clear and transparent. Through it could be seen the white opaque lens capsule resting on the deep surface of the graft. By the tenth day the graft had taken, but it did not appear as clear and transparent as before around its periphery. The graft appeared to be going opaque but there was a clear area in the centre. The patient complained of pain. Atropine oil was instilled and the eye firmly bandaged. As the tension remained +1 atropine was discontinued three weeks after the operation. Now the graft began gradually to clear. The tension however remained high for a further two weeks when it slowly returned to normal. The whole of the time during which the tension was raised the eye was firmly bandaged. Three weeks after the operation the patient was able to count fingers two feet away. At the present time vision remains the same and the graft is transparent.

COMMENTS

The method employed in this case has to my mind one great advantage. The conjunctiva when drawn over the graft brings nourishment through the lymph channels to the graft in the first few days when

the graft is taking. At the same time the conjunctiva protects the corneal epithelium from damage. The one great disadvantage is that when one has drawn the conjunctiva completely over the cornea and graft one is not sure that the graft has not been entirely dislodged from its bed or that it has not been even slightly tilted.

In a case of interstitial keratitis or in fact in most eye operations, iritis is likely to be produced. Atropine by dilating the pupil prevented anterior synechia.

The graft having remained clear I propose at some future date to extract the right lens.

This case was shown at the South Western Ophthalmological Society's meeting in December last.

CLINICAL AND LABORATORY NOTES

AN ABNORMAL LARGE INTESTINE
ENCOUNTERED DURING APPENDICECTOMY

By JOHN ALEXANDER MACKENZIE, Ch.M. Aberd.

SURGEON TO THE VICTORIA HOSPITAL, BURNLEY AND
TO THE HARTLEY HOSPITAL, COLNCE

ON Sept. 3rd, 1930 I was called to the Victoria Hospital Burnley by my house surgeon to see an acute abdomen.

The patient was a labourer aged 29 married with two healthy children. His mother had died of cancer at 36; his father was alive and well and his brothers and sisters healthy. Up to the age of 14 he had "incontinence of feces"; from 14 to 16 he was troubled with diarrhoea but from 16 to the present date he had been quite healthy. He was well built and healthy looking. He had a mitral murmur due to valvular incompetence but he was unaware of it and the condition had never given him any trouble. The urine was normal.

The temperature was 101 F the pulse-rate 120 and the patient had every classical symptom and sign of acute appendicitis. I operated at once and on opening the abdomen by a right para median incision was confronted with a much dilated large intestine which on tracing upwards went up below the liver and on tracing downwards went over the right side of the brim of the pelvis to form the rectum. I discovered the caecum behind this and partly covered by it.

reaching down to within an inch of the brim of the pelvis, while the peritoneum covering this large intestine shaded off from its mesentery over the caecum, covering it and fixing it down. At that point I could find no trace of the appendix, although the bowel showed inflammation. No small intestine was visible; but passing my hand in front of this dilated part of large intestine over to the left side I found all the small intestine congregated there and by tracing it found where it entered the caecum behind this dilated large intestine. On splitting the peritoneum where the small intestine joined the caecum in the acute angle pointing towards the umbilicus I found a small and acutely inflamed appendix which I removed. I resutured the peritoneum where I had split it and closed the abdomen as quickly as I could because the man was desperately ill.

The patient made an uninterrupted recovery and was later examined by barium meal. Fig 1 shows the barium leaving the stomach and making for the left side of the abdomen where the whole of the small intestine is collected. A second radiogram showed

FIG 1.—Radiogram after barium meal. Small intestine seen on right of abdomen.

FIG 2.—Barium meal filling the colon.

the meal entering the caecum behind and at the upper angle where the entrance was the dilated appendix was situated. It could also be seen passing up the ascending colon and into the transverse colon. A third radiogram showed the meal coming down the descending colon to the normal sigmoid flexure but when it reached the brim of the pelvis it

suddenly changed its mind and ascended transversely across the abdomen to the hepatic flexure, lying in front and covering the original hepatic flexure and descending in front and a little to the left of the caecum where it entered the pelvis on the right side to become the rectum. Fig 2 was taken after a barium enema and shows the splenic flexure and transverse colon also. In all the radiograms a large gland could be seen to the left of the vertebral column.

I have often found the sigmoid and rectum on the right side of the pelvis, especially in women, and in all these cases there has been a well marked mesentery. But I have never seen or read of any case like this, nor have I seen any developmental theory to explain it. Possibly the condition was the cause of the incontinence of faeces in early life.

I am indebted to Dr James Grieve, radiologist to the Victoria Hospital, for preparing radiograms for me.

CONTINUOUS VENOUS HUM IN CIRRHOSIS OF THE LIVER

By J L BATES, M.B. Lond.

RESIDENT PHYSICIAN, RUTHIN CASTLE, NORTH WALES

THE comparative rarity of a venous hum in cirrhosis of the liver and the question of its causation gives interest to the following case.

A man, aged 53, was admitted on March 11th, 1936, to Newcastle General Hospital under Prof. Thomas Beattie for swelling of the abdomen, noticed ten days previously, and dyspnoea on exertion. His increasing pallor and occasional attacks of giddiness had begun four months previously when he was obliged to give up his work as a turner and fitter. He had recently suffered from flatulence and intermittent diarrhoea. There was no history of haematemesis. The left leg had been amputated in 1926 at Newcastle Royal Infirmary for chronic osteomyelitis following a war injury. At the same time a blood test was performed and he was thereafter given a course of injections. He used to be a heavy beer drinker.

The patient was well built but appeared to have lost weight recently. The abdomen contained much free fluid and dilated veins were visible in both loins but not around the umbilicus. The distension made palpation difficult. Liver dullness not increased. Spleen not palpable. No cardiovascular abnormality. The pupils were equal but did not react to light. On auscultation of the abdomen, there was a continuous, loud, high pitched bruit with systolic and inspiratory exacerbation. This was heard only over an area the size of half a crown just below the xiphoid process.

Investigation.—A blood count showed red cells, 2,340,000; white cells 3200; haemoglobin, 20 per cent; colour index, 0.4; reticulocytes, 3 per cent. Blood urea 35 mg per 100 c.c.m. Urine contained a trace of albumin and occasional pus cells. Blood Wassermann, weak positive. Radiography of stomach and duodenum gave no evidence of ulcer or neoplasm. Occult blood test negative.

Treatment.—The patient was tapped on seven occasions between March 12th and June 5th. Small quantities were obtained at first but later up to 18 pints were withdrawn at a time and the ascites still increased. Shortly after admission he was given a blood transfusion which raised the haemoglobin to 50 per cent. He was given iron without visible improvement and later mercury and potassium iodide.

Various explanations have been offered to account for the bruit. Rolleston and McNee (1929) cite examples ascribed to dilatation of the coronary vein or a dilated communication between the internal mammary and radicles of the portal vein. Other authors have postulated an arteriovenous anastomosis which has not been substantiated post mortem. Rolleston and McNee also describe a case of con-

tinuous epigastric bruit in which post mortem examination showed cirrhosis of the liver and a thin walled vein in the falciform ligament as big as one's little finger. In a case described by Lutembacher (1936) the bruit was strictly localised in the xiphoid region and occurred in a syphilitic subject. In Florand's case it was of more widespread distribution and was audible posteriorly. Autopsy revealed a varicose plexus between the internal mammary veins and a persistent umbilical vein. Martini (1893) described a soft murmur over the liver near the right axilla which he ascribed to compression of the inferior vena cava.

Venous hum has been found in Hynd's cirrhosis and Banti's disease and has occasionally been heard only below the umbilicus or above the costal angle. The bruit may be compared with that heard in the left anterior axillary line in some cases of splenic enlargement. In the case outlined above I have tried to find the most probable explanation, taking into account the rarity and the strict localisation of the bruit. One factor may be the associated anaemia, but the transfusion had no effect on the murmur. If it were due to hyperplasia of the para-umbilical veins one would expect to hear it best over the "caput medusae," but the bruit was not heard at all over the umbilicus. It was not influenced by abdominal paracentesis. This suggested that the cause might be intrahepatic rather than lying in the anterior abdominal wall. Its rarity suggests its dependence on extreme hepatic fibrosis, which would be made more likely by the coincident specific infection.

A consideration of the "bruit de diable" heard where the jugular veins pass through the deep cervical fascia makes it seem probable that a venous bruit is caused by the passage of blood through a constricted lumen into a relatively dilated channel. The murmur in this case was heard at about the level at which the vena cava pierces the diaphragm. The vena cava is adherent to the margin of this opening and just below this the vessel receives the hepatic veins. I believe that the bruit is caused by stenosis of the vena cava by the perivenous hepatic fibrosis. The blood has to pass through this constricted part of the vena cava before entering the wider diaphragmatic hiatus.

I am indebted to Prof. Beattie for permission to publish this case.

PROGRESS AT THE MIDDLESEX HOSPITAL.—Prince Arthur of Connaught speaking at a court of governors of this hospital said that the work was increasing in every direction including that of cost. It was not possible owing to lack of funds to open to the full extent of the institutions 700 beds but 592 were at the public service and in patients numbered 9821 in 1936. The cost of the hospital and cancer wing was approximately £186,000 as against £106,000 a dozen years ago.

BEQUESTS TO HOSPITALS.—The late Mr. Caleb Diplock of Polegate, Sussex, has left many charitable bequests. Those to hospitals include £20,000 to Guy's Hospital, £8000 to St. George's Hospital, £5000 to the Royal National Orthopaedic Hospital, £4000 each to the Westminster Hospital and the London Hospital, and to the Middlesex Hospital. St. Bartholomew's Hospital and Charing Cross Hospital each receive £3000 and the Princess Alice Hospital, Eastbourne, £5000.

MEDICAL SOCIETIES

OPHTHALMOLOGICAL SOCIETY OF
THE UNITED KINGDOM

THE annual congress of this society was held on April 20th to May 1st under the presidency of Dr GORDON HOLMES F.R.S. who delivered an address on the

Prognosis in Papilloedema

He said that papilloedema was one of the common conditions which were a meeting ground of the ophthalmologist and the neurologist, and for academic and practical reasons concerned the practice of both. No aspect of the condition demanded more attention than its prognosis in regard to preservation of vision. Noteworthy contributions on the matter had been made to the society's Transactions particularly by Dr James Taylor and Mr Leslie Paton. The presence of papilloedema was often regarded as an immediate danger to vision and in different branches of the profession there was a good deal of misapprehension on the point. In this address the president proposed to discuss only that form of papilloedema which was associated with increased intracranial pressure leaving aside its diagnosis. The condition was now recognised to be essentially an oedema of the nerve head in which—for a time at least—there was little structural damage or functional disturbance of the nerve elements though these might be strangled and destroyed by overgrowth of interstitial tissue when the oedema subsided into atrophy. In the latter stage recovery of vision could not be expected. The essential aetiological factor in papilloedema was increased intracranial pressure therefore relief of that pressure would lead to a disappearance of the condition and so remove the risk of blindness or serious visual deterioration if the relief could be given before the development of secondary changes in the disc. Often there were cogent reasons against immediate operation. If the cause of the condition was a tumour its removal was frequently impossible especially if it were an extensive infiltrating one of the glioma type. In that kind of case operation quite often reduced the length and utility of life. Moreover operation even in the most skilled hands entailed considerable risk to life. To the question of how long measures for relieving pressure could be delayed without endangering vision no general answer could be given. Even intense oedema might not cause any disturbance of vision as was emphasised by Hughlings Jackson 48 years ago. Vision indeed might remain unimpaired for long periods. In rare cases the papilloedema subsided without surgical intervention or other specific treatment and vision remained unaffected. In most of these cases it was impossible to ascertain the exact nature of the condition to which the papilloedema was due. In some there might be a tuberculous or gummatous tumour which became quiescent or a glomatous growth which degenerated but intracranial hydrocephalus was probably responsible in many of them for the raising of intracranial pressure. In others there might be an external hydrocephalus or a serious meningitis.

In most cases of papilloedema relief of intracranial pressure was necessary or soon became so in order to save sight and the important question arose of recognising the time when further delay was dangerous. The more rapidly the congestion and swelling of the optic

disc developed the more intense did the papilloedema become and the greater the danger to sight if no relief were undertaken. A swelling of 4 or 5 diopters was a warning against undue delay. Equally serious was great engorgement of retinal veins and early and extensive hæmorrhages on the surface of the swollen disc. An even more important danger was a narrowing of the arteries in the swollen disc and its vicinity. Frequent examination should be made in order to evaluate the fundal changes and detect the earliest signs of secondary atrophy. A further serious sign was the transient loss of sight complained of by many patients. This might follow sudden changes of posture. If the tumour or other cause of the increased pressure could not be removed by extirpation a decompression craniectomy usually caused subsidence of the congestion in from two to four weeks and if secondary changes had not appeared by then there was no further risk of impairment of vision.

Papers were read by Mr R. FOSTER MOORE and Mr J. COLE MARSHALL on the

Treatment of Retinal Detachment

Mr Foster Moore's communication summarised some observations on the technique of karyolysis in the treatment of retinal detachment and on the early results obtained in 31 cases. The object of the procedure was to produce coagulation in the choroid as the result of the liberation of sodium ions at the negative terminal inserted through the sclerotic at the same time hydroxyl ions were set free. The apparatus he used was made by Messrs Hamblin; the needles were either straight or bent at a right angle. The length of the active part of the needle varied from 1 mm. upwards; they were made of platinum-iridium. The best strength of current he had found to be 5 milliamperes, usually he passed it for six seconds. An almost unlimited number of punctures could be made even though the eye might be rather soft. The flaccidity might make subsequent trephining difficult. Bubbles of gas were seen at the site of the puncture from which there was always some escape of fluid when the escape was free no additional exit was required for the subretinal fluid. But it was better to make a definite hole by trephining or with the galvanocautery. Of the 31 cases, 14 were myopic. In 12 of them the retina was replaced and remained in position when last the patient was seen. 2 were discharged slightly improved, 4 much improved, 9 not improved. But the longest period since the treatment was not more than twelve months and in many of them only a few weeks. The advantages of the method were that the apparatus was light portable and easy to use. Its effects were sharply localised and less damage was done to intra-ocular tissue than with diathermy. It was unnecessary to divide the muscle unless exposure was needed of the sclerotic far back. The crucial test however was not in how many cases the retina went back, but in what proportion the replacement was permanent. To that question he had at present no answer.

Mr Cole Marshall said that in karyolysis the whole length of the needle was active not only its base. A keratiti was formed and a retinitis round the region where the bubbles had been liberated which might subsequently cause changes in the choroid. Mr Foster Moore appeared to retain the needle in the eye longer than did most continental operators and to use a slightly stronger current. Karyolysis

was not only a good localising agent but a good adjunct to diathermy scarring. Mr Marshall had found katholysis very beneficial in conjunction with diathermy, using very fine needles for the latter. The transillumination method described by Weve he regarded as very important, as also was the continuous use of saline during the operation, this being applied every minute.

On April 29th a discussion on

Exophthalmic Ophthalmoplegia

was opened by Dr W. RUSSELL BRAIN. He said that in this condition exophthalmos and ophthalmoplegia might be either unilateral or bilateral. General symptoms of thyrotoxicosis, usually slight, might be present if the condition arose spontaneously, if it followed thyroidectomy for hyperthyroidism such symptoms were often absent, the basal metabolic rate being normal, or even subnormal.

The separation of exophthalmic ophthalmoplegia as a syndrome from exophthalmic goitre depended on a number of features, the most important of these being that it might occur after operation not only in the absence of thyrotoxicosis but in the presence of actual hypothyroidism. It also differed from Graves's disease in its age incidence and its sex-incidence, in the usually slight degree of the thyrotoxic symptoms when present, in the usual lack of response to thyroidectomy, and in the somewhat atypical histological picture in the thyroid. Exophthalmic ophthalmoplegia was a disorder of middle age. The mode of onset was usually subacute, one eye became increasingly prominent over a period of three to four months, the ophthalmoplegia and the double vision developing concurrently. Generally the other eye lagged behind in the matter of proptosis, and might not exhibit ophthalmoplegia at all. Both exophthalmos and ophthalmoplegia might develop simultaneously in both eyes in three or four months. Exophthalmos was present in all Dr Russell Brain's cases: unilateral in 5, bilateral in 24. Among the latter the degree of exophthalmos was equal in 8, unequal in 16. An asymmetry of the eye protrusion was present in 21 out of 29 cases. The ophthalmoplegia was a paresis or paralysis not of individual extraocular muscles but of movements of the eye in a particular plane. In the 12 unilateral cases, elevation was the movement most often affected; in the 17 bilateral cases abduction was affected 31 times, elevation 23 times, depression 18 times, adduction 17 times. In 6 patients all movements of both eyes were affected. Widening of the palpebral fissures with retraction of the upper lid was the usual finding in both unilateral and bilateral cases, but ptosis was present on both sides in 5 cases, and on one side in 3 cases with bilateral ophthalmoplegia. With regard to the pathology of the ocular muscles the changes consisted of marked oedema, with foci of lymphocytic infiltration, and, in later stages, fibrosis. In one portion of levator palpebrae superioris removed at operation Prof H. M. Turnbull found general oedema and great enlargement of muscle fibres. In 4 out of 5 cases sections of the thyroid gland examined by Prof Turnbull showed that the gland was atypical, and in the other case the gland was the same as in Graves's disease.

The usual treatment given for exophthalmic goitre had been, in his experience, disappointing when applied to exophthalmic ophthalmoplegia. Thyroidectomy was done in 4 cases. In one of them there was distinct general improvement and considerable improvement in the condition of the eyes though some ophthalmoplegia remained. Following orbital

decompression there occurred an immediate recession of the eye, but the ophthalmoplegia remained unchanged in one case and was only moderately benefited in the other two. Dr Brain looked forward to the day when the condition could be dealt with in a more physiological manner than by surgery.

Prof. F. R. FRASER gave a general survey of the similarities between toxic goitre and myasthenia gravis and said that he had been able to test the effect of prostigmin on two patients with toxic goitre. The first was a woman aged 41, who had begun to show signs of toxic goitre—tremors, palpitation, and marked sweating—at the age of 26. A year later she developed exophthalmos, more marked on the right side, diplopia, and a pronounced ptosis of the left upper eyelid. The ophthalmoplegia progressed rapidly and interfered with her work as a teacher. The drooping of the eyelid became more marked towards the end of the day, and at the end of the school term the diplopia was much more severe. In 1925 ophthalmoplegia definitely improved after partial thyroidectomy, and the ptosis improved so much that she could resume teaching. The tachycardia and tremors, however, never disappeared. She was accordingly treated with prostigmin (2.5 mg.), a large dose whose possible upsetting effects were countered by atropine administered some 20 minutes beforehand. Four minutes after giving the prostigmin there was improvement in the upward vertical movement of the right eye, in a few minutes the axes of the eyeballs became parallel on looking straightforward, there was a twitching of the orbiculars, and diplopia was only present when the patient looked above the horizontal. Seventeen minutes after the injection diplopia was only to be found on extreme upward elevation of the eyes. At that stage the patient began to go back a little, as diplopia could be elicited more easily, and after half an hour the axes were again deviated. She said that during the rest of the evening her eyes were stronger. A week later a similar dramatic result was achieved. The second patient was also a woman aged 41, whose toxic goitre had developed 9 years previously, beginning with a feeling of weariness. A year later exophthalmos was noticeable, without severe toxicity. Then diplopia appeared. Thyroidectomy was carried out in 1930, and since then the ophthalmoplegia had remained stationary. During the last few years the patient had been treated with thyroid because of lassitude and general depression, and in the last year the exophthalmos had become more pronounced than ever before. Prostigmin had no effect. The difference in results in these two cases suggested, Prof Fraser said, a different pathology, or that the disease process in the second patient had so progressed that it could not respond.

Mr H. B. STALLARD also described a case of exophthalmic ophthalmoplegia in a man aged 31 in whom the thyrotropic hormone of the anterior lobe of the pituitary stimulated the thyroid gland, increasing the exophthalmos, and causing typical thyrotoxic manifestations.

The PRESIDENT said that in a certain proportion of cases of proptosis of the eyes there were very few other symptoms of thyrotoxicosis, notably the pulse rate was not increased. Possibly there were three types of case. Prof Fraser had shown that different reactions might follow the use of prostigmin, thus indicating two classes, and he had seen instances of a rarer condition characterised by definite weakness

of some of the ocular muscles with rapidly developing exophthalmos some subluxation of the globe had been described in cases of thyrotoxicosis. He considered that the transient palsies were due to a sudden stretching of the muscles due to mechanical causes in the orbit itself. As to pathology Sir William Gowers had referred many years ago to the possibility of a primary degeneration of the cells occurring in these cases. Vigor demonstrated leucocytic infiltrations in myasthenia gravis; but Mr Stallard had said the muscle fibres in his case did not show pathological change. The question whether there was a change in the nervous supply of the muscles had not been answered. In ophthalmic ophthalmoplegia there was some variability of the symptoms several patients said their ocular movements were fuller in the morning than when they were tired at the end of the day. This exhaustibility of ocular movements brought these cases more into line with myasthenia gravis as Prof Frazer had said.

The Nettleship Medal

During the congress the President presented the Nettleship Medal to Mr H B Stallard, particularly for his work on the treatment of glaucoma of the retina by radium emanations.

GASTRO ENTEROLOGY WEEK IN FRANCE

The International Society of Gastro-enterology has organized its second congress which will take place in Paris during the Universal Exhibition on Sept 13th, 14th and 15th under the presidency of Prof Pierre Duval (Paris). The subjects for discussion will be early diagnosis of cancer of the stomach and it will be dealt with by French and German speakers. The collected reports of the French contributors will be presented by Prof Duval and Prof Goesset with the collaboration of Prof Carnot (clinical and serological diagnosis) Dr Gutman (radiology) Dr Moutier (gastroscopy) Dr Garin (photographic gastroscopy) Prof Labbé (chemical diagnosis) Dr Yvan Bertrand (pathological histology) and Dr Gatellier and Dr Charrier (operative diagnosis). Prof Konjetzny will present the collected reports of the German contributors with the collaboration of Prof Sauerbruch (surgery) Prof Buerger (chemical diagnosis) Prof Berg (radiology) Prof Henning (gastroscopy and gastrophotography) and Prof Stammier (pathological anatomy). The second subject for discussion will be intestinal obstruction and Dr Mogana (Spain) will deal with it from the medical side. Dr Bottin (Belgium) from the physiopathological, Dr Kryzski (Poland) from the radiological, Sir David Wilkie (Great Britain) from the surgical and Prof Blindo de Vecchio (Italy) from the pathological-anatomical.

At the end of the Paris congress the International Congress on Liver Insufficiency will meet at Vichy on Sept. 16th, 17th and 18th under the presidency of Prof Loeper. It will have a medical and a therapeutic section and the subjects for discussion will be hepatic oedema, the malarial liver, enlarged liver in children, sulphur metabolism, the liver from the point of view of surgical intervention, and hepatic drugs.

Dr A F Hurst is president of the British committee of the society and Dr T G Hunt 49 Wimpole-street London W 1 is the hon secretary.

JOURNÉES MÉDICALES INTERNATIONALES DE PARIS
A conference organized by the Revue Médicale Française will take place in Paris on June 20th to 30th and will discuss the biological, clinical and therapeutic action of hormones. The itinerary includes sessions at which papers will be read and visits made to appropriate centres. Communications from those requiring detailed information should be directed to Dr Louis Lamy, treasurer of the Journées Médicales 18 Rue de Valenciennes, Paris, accom-

NEW INVENTIONS

T TUBE FOR GALL BLADDER OPERATIONS

THERE are several types of T tube for draining the common bile-duct, most of these being modifications of Kehr's pattern. During the last few years the indications for exploration and drainage of the biliary ducts have been greatly extended and this is now rarely omitted in operations for cholelithiasis as soft pigment stones, collections of biliary and inspissated pus and inflammatory debris cannot always be palpated, even when present in large amounts.

The T tube I use is the thickness of No 7 English catheter gauge and it is 25 in in length. The

transverse trough-shaped piece is 2 in long and is fitted obliquely to the tube. The soft rubber trough is easily inserted into the incision in the common duct, being securely fixed into position by stitching over it the edges of the incision in the duct by means of a few interrupted catgut sutures. The long limb of the tube is led through the abdominal wound or through a special stab wound and is anchored to the skin margin to prevent it from being inadvertently withdrawn. By means of a glass connexion which is attached to another length of rubber tubing the bile is made to drain through into a small medicine bottle which is fixed to the patient's side or to the bed. Some of the bile thus collected is returned per rectum two or three times a day. I find this tube very easy to insert into the common duct; and, what is more, it is easy to remove after it has done its work. Provided there is no obstruction in the lower reaches of the duct there is no discharge of bile through the wound after the tube has been withdrawn.

The tube is made to my specification by Messrs John Bell and Croyden Wigmore-street London W 1

RODNEY MANNING F.R.C.S. Eng.

Senior Surgeon to the Royal Waterloo Hospital and to the Southern General Hospital.

panied with the necessary fee by cheque or postal order. The fee for admission to the Congress for doctors is 100 Frs; the subscription for medical students and for the wives and children of doctors is 50 Frs. Admission will secure for the applicants admission to all the sessions and to various pleasure reunions which include a performance at the Théâtre des Champs-Élysées, a reception by the Municipal Council of Paris and an evening visit to the Louvre.

REVIEWS AND NOTICES OF BOOKS

1 **Cushny's Text-Book of Pharmacology and Therapeutics**

Or the Action of Drugs in Health and Disease
Eleventh edition By C W EDMUNDS, A B, M D,
Professor of Materia Medica and Therapeutics and
Director of the Pharmacological Laboratories in
the University of Michigan, and J A GUNN,
M.A., M.D., D.Sc., F.R.C.P., Professor of Pharma-
cology and Director of the Nuffield Institute for
Medical Research, University of Oxford London
J and A Churchill 1936 Pp 808 25s

2 **An Introduction to Pharmacology and Therapeutics**

Fifth edition By J A GUNN London Humphrey
Mifflord, Oxford University Press 1936 Pp 240 5s

1 A thoroughly revised edition of this standard work was published in 1932 when it was also brought into conformity with the new British Pharmacopœia. The eleventh decennial revision of the Pharmacopœia of the United States has made another edition desirable. The most striking change is a rearrangement in the order of the book. It is not yet possible to arrange substances used as drugs in any strictly scientific way and in whatever order they are arranged some repetition is inevitable. In this edition the simpler substances—e.g., salts and inorganic compounds—are dealt with first and the more complex substances later. On the whole, this rearrangement is an improvement on the plan of previous editions.

The book has been brought up to date in several important respects. For example, a fuller account of acetylcholine and its derivatives is given than in previous editions, and the use of derivatives of physostigmine in myasthenia gravis is dealt with. New amebicides such as Carbasone, Chumofon, and Vioform receive full discussion, and protamine insulinate is mentioned. There is in fact hardly a section which does not show signs of revision. Excellent accounts of the vitamins and hormones are given. It is curious to find no mention of the sex hormones, especially as the gonadotropic factors of the anterior lobe of the pituitary are described. A commendable change is the introduction of structural formulæ for the alkaloids and other substances where these are known. The bibliography which follows each main section has mostly been inherited from Cushny's original book although several more recent references have been added. Its value is doubtful, since few medical students are likely to refer to original papers for information and the number of references given are too few for the research worker, who is more likely to consult a larger work. The authors, however, recognise this defect and have tried to remedy it to some extent by giving as many references as possible to reviews which themselves contain a good bibliography. The book thoroughly deserves the high esteem in which it is held by teacher, student, and practitioner alike.

2 This little book is well known to examiners in pharmacology since too often it seems to be the sole source of information to which the candidates have had recourse. This fact cannot be laid to the author's charge for he indicates clearly in his preface that the book is intended only to supplement the student's lectures or reading. It is, in fact, quite unlike the usual "cram book," for brevity has been achieved by judicious selection and not by mere compression. It affords an excellent introduction to pharmacology, and when properly used for purposes of revision can

hardly fail to help the student. It can be heartily commended, too, to the practitioner who wishes to survey rapidly the changes which have taken place in recent years in our knowledge of drugs. The exhaustion of the previous edition in only two years has provided the opportunity of making minor revisions and of bringing the book into accord with the revised United States Pharmacopœia. The changes are few and the author is to be congratulated on resisting any temptation to expand the book.

Occupational Diseases

By DONALD HUNTER, F.R.C.P. London H K
Lewis 1937 Pp 122 9s

THIS book consists of a reprint from the *London Hospital Gazette* of a series of lectures delivered to the Derby Medical Society during 1935. A surprising amount of useful information on a very wide variety of industrial medical subjects is presented in a readable form. The illustrations (of which there are many) are good in themselves and excellently reproduced. The lectures were not designed for specialists in industrial medicine, although few even among experts could fail to glean valuable knowledge from them. In the first lecture Dr Hunter discusses lead, arsenic, and (very briefly) phosphoretted hydrogen, in the second metal poisonings, industrial infections, and deficiency diseases are rapidly surveyed. The third lecture deals with a wide variety of subjects, including some of the "dust diseases," the toxic gases, benzene, aniline, and the chlorinated hydrocarbons, and in the last a number of topics including cancer, dermatitis, nystagmus, Workmen's Compensation, and the prevention of industrial disease are reviewed. It is obviously impossible to deal profoundly in a little over 100 pages with so wide a field.

The book will prove especially valuable, we think, to practitioners in industrial areas or works, and certifying or examining surgeons. We must join issue with the author upon one major and a number of minor issues. The major issue concerns the diagnosis of industrial lead poisoning. To suggest that a diagnosis of lead poisoning cannot be established unless one of the toxic episodes has occurred (see p. 11) is, we believe, contrary to modern industrial medical opinion. The work of R. E. Lane and others enables a diagnosis of lead poisoning to be made before the occurrence of a toxic crisis. A falling Hb per cent, with or without a rising "punctate count," in a worker exposed to lead raises a suspicion that "absorption" is passing over into "poisoning." This suspicion becomes a certainty when these changes are well marked or can be shown to be progressive. This is a point of considerable medico-legal importance. The minor points are the following: metal fume fever is now known to be caused by other metals besides zinc (e.g., cadmium and magnesium), the "sericite" theory of the causation of silicosis rests upon a less solid basis of fact than Dr Hunter appears to suggest, the Kolar Gold miners suffer from pneumoconiosis, the clinical dictum that occupational cramps "are always associated with anxiety to get the work done in time and up to standard" would be seriously questioned in many quarters. Dr Hunter's "15 point summary" of the prevention of disease in industry must not be taken as an adequate summary of the potential contributions of industrial medicine to industry.

As we have said this book provides a useful clinical summary of that part of industrial medicine which is concerned with the diagnosis of the recognised diseases and toxæmias of occupation. We hope that it will have a wide circulation amongst industrial practitioners concerned with the prevention and treatment of these conditions.

Christian R. Holmes, Man and Physician

By MARTIN FISCHER. Springfield, Ill. Charles C. Thomas. London. Bailière Tindall and Cox. 1937. Pp. 233. 5s.

THIS is a sumptuous memorial volume in format, printing and binding. It is fortunate that the subject of the biography led a life of single minded absorption in a great ideal or the terms of eulogy would seem unduly high. Dr Christian Holmes was the centre of medical progress in Cincinnati. The son of a Danish immigrant he was 15 years old when he landed with his father in New York. He had been well taught and having considerable skill as a draughtsman he secured work at once in the designing rooms of a civil engineer. As a young man work as a self taught engineer brought him to Cincinnati and in 1879 he began to read medicine at what was then a rather primitive centre. On qualification he became resident in the Cincinnati Hospital and for the rest of his life he was connected with the institution and devoted to its development. In practice he was energetic and versatile and quick professional success enabled him to pay regular visits to the chief medical centres in Europe with the result that he took the lead in a movement for the construction in Cincinnati of a new central hospital. The details of this work—how public support was obtained and how Holmes organised a financial backing—make an interesting story and show him to have been a man of initiative, drive and perseverance. Soon a medical college arose in connexion with the hospital and in 1910 Holmes was able to claim for the students of medicine in Cincinnati that they had facilities for clinical study of a high standard, laboratories available for teaching and research and a fine corps of instructors. Christian Holmes died in 1920 having devoted 40 years to the object which he set before him almost at the outset of his career—to establish in Cincinnati a first-class medical centre.

Cytologie du liquide céphalo rachidien normal chez l'homme

By H. JENSEN (Aarhus Denmark). Paris. Masson et Cie. 1936. Pp. 168. 1r.40.

If the scope of this monograph is limited the work it describes is nevertheless important. Dr Jensen deserves thanks for carrying through a laborious task which many would find uncongenial. The book has three sections dealing respectively with the morphology, enumeration and probable function (or lack of function) of the cellular constituents of normal cerebro spinal fluid. An exhaustive account and criticism of the various technical methods for dealing with the fluid justifies the author's contention that the subject is in a state of great confusion attributable to the tendency of the cells to rapid degeneration and the consequent medley of different classifications and results according to the methods used by various observers. He himself has worked on about 500 individuals after having selected what he believed to be the best techniques and modified them for his purpose. His reasons for his choice are convincing and since he indicates

wherein they are unsatisfactory subsequent investigators are not likely to accuse him of making exaggerated claims for them. The same moderation characterises his general conclusions. He finds that there are three types of cells: (1) those resembling and possibly identical with lymphocytes; (2) larger cells resembling the large lymphocytes of the blood but probably of epithelial origin; and (3) irregularly shaped cells characteristic of the cerebro spinal fluid, whose nature and origin can only be surmised. All three are very variable in number both in different individuals and in the same individual at different times and all tend to degenerate very rapidly *in vivo* and *in vitro*. Other types of cell such as granulocytes are always the result of contamination. A count of more than 10 cells per c.mm. is pathological and between 5 and 10 per c.mm. suspicious but extensive variations below these concentrations are common and not significant. In view of the ample opportunities of the cerebro spinal fluid to pick up cellular elements from the meninges during its circulation their occurrence and number must be regarded as fortuitous in the absence of definite evidence to the contrary and no function can be ascribed to them.

Although the outcome of this study seems meagre in comparison with the amount of labour involved the monograph gives an excellent review of the subject, contains much sound and critical discussion of technical matters and has an exhaustive bibliography. It will be of distinct value to those interested especially in the cerebro spinal fluid and furnishes a much better basis than has hitherto existed from which to start pathological and diagnostic studies.

A Dissertation on the Sensible and Irritable Parts of Animals

By ALBRECHT VON HALLER. Baltimore. Johns Hopkins Press. 1936. Pp. 49. 8s.

THIS is a pleasing reprint of a minor neurological classic and its interest is much increased by an excellent introduction by O. Temkin. Originally published by von Haller in 1752 when he was professor of physiology at Göttingen it was translated into French and thence into the English version of 1755 which is here reproduced. Haller's thesis was that only those parts of the body which have nerves possess sensibility while irritability is a property of muscle. It was a clarifying conception if only because it at once aroused serious and substantial criticism. Surgeons challenged his facts—e.g. about the insensibility of pericæum—while experimentalists rightly objected to the narrow interpretation of irritability. His work was indeed a stepping stone so wobbly that it led others to build a bridge and it is now of little more than archaeological moment. The reprint has some high interest for the title page is reproduced in facsimile and shows the stamp of the Warrington Dispensary Library reminding us of the pioneers in medicine and education who brought fame to that grim town 160 years ago.

Dr Argyll Campbell and Dr J. P. Poulton have written an addendum to their book *Oxygen and Carbon Dioxide Therapy* reviewed in our issue of March 2nd 1935. It is entitled *The Oxygen Tent and Nasal Catheter* and will be supplied gratis to purchasers of the book who apply to the Oxford University Press, Amen House, Warwick Square, London, E.C.4.

MEDICINE AND THE LAW

Epilepsy and Criminal Responsibility

IN *R v Edwards* the accused was found guilty at Leeds assizes last March of having murdered his fiancée. The defence did not dispute that the dead woman met her death at the hands of the accused man. The evidence, however, showed that he and she had been on the best of terms and no motive could be assigned for his violence. It was suggested at the trial that there was a long history, from the time the accused was three years old, of entirely unprovoked attacks ending in some kind of fit or hysterical seizure involving unconsciousness. It was proved that a relative of Edwards had died of fits. The defence called two doctors who came to the conclusion that Edwards was an epileptic subject. All the medical witnesses agreed that, if the attack had been committed during an epileptic seizure, it was committed at a time when he was incapable of forming an intent. These considerations were put forward on his behalf in the Court of Criminal Appeal, with the argument that the jury should have been directed at the trial upon the question of the proof of intent, it was contended that the trial judge should have told the jurors that, if they were left in doubt whether the attack was committed during an epileptic seizure, they could not return a verdict of murder because the requisite intention would not have been proved.

Lord Hewart dismissed this argument. He regarded the defence of epilepsy as a defence of insanity, and he repeated what he has so often said before—namely, that the burden of establishing the defence of insanity is always on the defence. It is now suggested, he said, that although an inchoate defence of insanity fails and the proof of it is not made clear, it may nevertheless leave the minds of the jury in a state of flux or uncertainty, so that they can find a verdict of either "not guilty" or "guilty of manslaughter." That proposition is not the law, nor can it be permitted to undermine the well known rules in *McNaghten's case*.

Psychology in Prisons

While the criminal law thus continues to recognise at assizes and in the Court of Criminal Appeal only one species of insanity and to require strict proof of the existence of this insanity from the accused, the annual report of the Commissioners of Prisons, just issued for the year 1935 (Cmd. 5430, 2s), contains a corrective. "It would be helpful," writes the Medical Commissioner, Dr W. Norwood East, in his important contribution to the report, "if justices and police authorities remembered that the diagnosis of the mental condition of an accused person does not rest merely between sanity, insanity and mental deficiency." He then proceeds to set out the classification of psychoses encountered and identified by the medical officers of English prisons. Dr East, as his previous reports have shown, approaches with caution the psychiatric treatment of crime. Necessary and useful as it may be, he regards it as a dangerous weapon when it leads people to believe that benefits will follow although failures outnumber successes. He reasserts his view that psychiatric treatment of criminals must follow the method of science and that it has as yet produced no impressive series of carefully tested results. In the first half of the nineteenth century the phrenologists claimed that their

doctrines could be applied to analyse the nature of certain crimes and to provide a sound judgment of the appropriate punishment. After the phrenologists came the anthropologists with fresh speculations on the cause and prevention of anti-social conduct. Dr East would have us test the application of psychological medicine to criminal mentality by the same scientific method as might have exposed the inadequacy of conceptions formerly fashionable. He commits himself to the definite statement that psychological treatment is unnecessary and undesirable in the majority of criminal cases. All will not agree with him even after considering his elaboration of the following points which affect the medical profession. Sometimes a court postpones sentence in order that an opinion on the prisoner's suitability for psychological treatment may first be obtained. Then, having been furnished with medical evidence and advice which favours such treatment, the court occasionally imposes a sentence of imprisonment nevertheless. The result is that the prisoner thinks that he might have escaped prison but for the medical evidence, hostility follows, instead of coöperation. Again it sometimes happens that a defending advocate urges that an accused man requires medical treatment rather than imprisonment, medical witnesses are exploited in support of such a plea in cases which are unsuitable. Here, too, hostility is the natural sequel if imprisonment is imposed. The prisoner tries to obtain preferential treatment on the strength of the medical opinions, when this is refused, he is inclined to attribute his future conduct to medical ineptitude. Alternatively, if the court does not send him to prison, no useful purpose is served by non-effective treatment at a clinic or elsewhere. The Medical Commissioner closes his report with further significant reminders. Abnormal behaviour may be due to group conduct as well as to individual conduct. It is common experience that persons will, as members of a gang, commit offences which they would hesitate to undertake of their own motion. Such cases may more properly be dealt with by change of environment than by prolonged psychological investigation. Secondly the comfortable doctrine of self-expression gives anxiety if it discounts the value of self-control. Criminals are all too ready to avoid reality and to refuse to acknowledge their own fault. The psychologist's examination, after all, may explain criminal conduct but is not meant to excuse it. Lastly he observes that present-day psychotherapy is practised by some who have no medical or psychiatric training. Only medical experts, he reasonably contends, should assess and give evidence on the mental condition of accused persons in relation to their suitability for psychiatric treatment.

WEST CORNWALL MINERS' AND WOMEN'S HOSPITAL, REDRUTH—Commander Sir Edward Nicholl has cut the first sod of the extension to be built at this hospital. He has contributed £15,000 towards the cost. The number of beds will be increased from 57 to 91.

FUND FOR SPA TREATMENT—Miss Sophia Gifford Edmonds, London, has given the sum of £500 a year to enable poor persons living outside a radius of fifty miles from the town to obtain treatment at Droitwich Spa. The fund will be known as The Droitwich Brine Fund for the Treatment of Rheumatism. As only a limited number of patients can be accepted under the scheme, participation in it is being offered to certain general hospitals in England and Wales. The founder hopes however that in time other charitably disposed persons will be led to enlarge its scope.

THE LANCET

LONDON SATURDAY MAY 8 1937

ON CROWNING THE KING

THE KING the fountain of honour has honour bestowed on him by his people only once—at coronation. At other times he receives their gifts of honour as a tribute to the Crown. The ceremony of the Coronation serves two purposes—it brings the person of the king within range as it were by doing something to him and its traditional elaboration makes the act of more than local or topical significance. By following custom we bridge the generations and lift the immediate occasion out of the present making it—and ourselves—a part of a timeless age long and therefore solid relation between the Ruler the Head of the Family and his people. The ceremony itself satisfies the desire to express something of the mystical reverence which lies deep—often deep hidden—in the human heart. However modern our outlook however little ceremony may mean to us as individuals its value in public life cannot be denied. It helps the separate individuals in the community to identify themselves with one another by adopting the same attitude to the Ruler. The sense of relationship to other members of the community gained by making the Ruler a common ideal, is one of the factors which stabilise an empire however distant are its constituent parts. The maintenance of this common ideal cannot be achieved without effort on the part of both ruler and peoples. The ruler on his side must not be merely a remote figure head, nor may he fall below the ideal standard the people have set for themselves. The model must be both worthy and capable of being copied—it must be human. The people for their part must resist a tendency, which may at first seem harmless to over idealise or to exalt to deistic proportions those who hold positions of authority. This tendency is a legacy from childhood and is accompanied by another relic of our primitive nursery impulses—a wish to control the behaviour of the being thus exalted. Doctors have a special opportunity for observation of this in daily life when a person holds this or that parent too high above criticism he regards

himself as specially fitted to manage the affairs of the person he adores. So it is in the constitutional relationship—groups which claim to possess a superior kind of loyalty or a more mystical understanding of the true nature of the Royal heart and mind also claim as of right to interpret the Royal will. Such an attitude is dangerous to constitutional development because its arrogance is concealed behind a mask of apparently generous intentions. We have to go back to the nursery in order to understand the basis of the monarchical form of government which draws its strength from a displacement of the ties of the family—the group in which we begin our social experience—to the central government of our national life. In the much used phrase 'the King is the Father of his People' there is a profound psychological truth. The wish to reanimate in the national life the intense experience of veneration once felt in nursery life towards the father exerts a powerful influence on our social institutions.

The smooth flow of corporate life which has for the most part characterised British history in recent centuries, obscures the strong forces which lie beneath the surface. Priding ourselves rightly perhaps on bringing to public life a sturdy common sense we tend to take institutions for granted unless either they begin to fail in their purpose or an external event calls them to our notice. We have moreover found a means of preserving an equilibrium in our relations to the governing authority which other nations do not so fully employ. The political part of our emotional life is split into two—one portion is reserved for the Crown and all that it implies the other for the Cabinet. Thus even acute discontent when it arises does not destroy the whole of the sovereign power but only a replaceable portion of it—we only turn out a party government. The parliamentary system is safe so long as it does not absorb the whole of the political sentiment of the people or receive the full force of popular opposition the throne is safe so long as the cabinet is strong enough to be worth attacking. This view may help to resolve some of the difficulties of the jurists and philosophers of the past and bring them into a new alignment. Blackstone examined the royal prerogative which invests our Sovereign Lord thus all perfect and immortal in his kingly capacity. Paley remarked that these formidable prerogatives dwindle into mere ceremonies while Bagehot coming nearer to our modern views described the limits of royal power and explained its function in terms of loyalty.

In our Empire the KING is above politics, and we have in the last century been favoured with a Royal House which has understood its responsibility as that of exacting only loyalty as tribute and giving life-long service in return. A constitutional monarch is like the father of a *grown-up* family, his power depends on his behaviour. So long as that is determined by consideration of the common good he receives the devotion of his children based on their respect for one who gives them all an equal share of his good regard. The British preserve a human relationship and a family feeling for their Ruler, neither debasing him into a puppet nor turning him into a god. King GEORGE VI is the head of our family and in crowning him we honour him, our constitution, and ourselves.

OBSTETRICS IN GENERAL PRACTICE

THE Ministry of Health's report on maternal mortality is more revolutionary than may appear at first sight. It says that many women die unnecessarily through childbirth, and that if they are to be saved the first need is better midwifery. It makes a recommendation that in blunt words means this—that public authorities shall no longer pay a doctor to attend a confinement unless he is known to have special ability for the task. At present when a midwife wants medical help she has to call in whatever doctor the patient chooses, and the local authority pays. The Ministry is evidently going to propose that in future the midwife shall only be able to call a doctor whose skill in midwifery is recognised in the neighbourhood. If local authorities are to pay for pippers they will henceforth have a say in choosing them, and will ask that their tune shall harmonise with what is being played by the rest of their orchestra, consisting of midwives, consultants, and hospital officers. The new Midwives Act and the new training rules of the C.M.B. will secure greater efficiency from midwives by providing better trained, better organised, and fully employed women. The local authorities under whom they work will want to strengthen the vital link between midwife and consultant by selecting from the available local talent a limited number of the best qualified practitioners to come to their aid when required. In other words, they will no longer accept a registrable medical qualification as sufficient evidence that a man is competent to practise difficult midwifery. The significance of this proposal needs no underlining. It must be recognised as a big step towards the removal of midwifery from ordinary general practice.

What has led the Ministry's investigators to favour such a step? From the summary appearing on p. 1126 it will be seen that they made a laborious inquiry into all the maternal deaths in certain areas during 1934 and found much to criticise in the conduct of pregnancy, labour, and the puer-

perium. Their observations are consistent with the results of the analysis of nearly 6000 maternal deaths made by the Departmental Committee in 1932, when it was estimated that in nearly half the cases there was a "primary avoidable factor." But the study of failures does not reveal the whole truth, as the Ministry's medical officers would be the first to admit. An examination of 700 fatal cases of appendicitis would probably suggest that everyone with a pain in the stomach should at once see a surgeon, yet this would be nonsense. The evidence of failure provided by these surveys is *supporting* evidence, but is not in itself enough. The true argument in favour of taking midwifery out of ordinary general practice is this. The birth rate is falling, more and more women are being delivered in hospital or by midwives alone, the number of general practitioners is increasing, and so is the volume of their work. The result is that many practitioners deliver very few women in the year, and some are called only to abnormal confinements. Many of the younger men, although they feel obliged to undertake such work, have had too little experience of midwifery to be competent in emergencies that may tax the most skilful—and these emergencies are often encountered in the very difficult circumstances of poor homes. The medical student's instruction—however much is squeezed into it—does not turn out an obstetrician but only a man capable of becoming one. Unless he has special post graduate training or a long experience of unselected cases, he cannot be regarded as the proper person to go to the rescue of a midwife. Occasional obstetrics is even more dangerous than occasional motoring, and the conduct of labour should be undertaken only by those who are genuinely interested in it and willing to give it time and thought.

These arguments are familiar enough, and there are good answers to them. The British Medical Association's scheme for a maternity service is based on every woman having her own doctor to attend her before, during, and after confinement, and its exponents emphasise the value of this continuity of care. Where, as often happens, a practitioner takes a pride in his midwifery, and does not allow other duties to deflect him from it, he can certainly offer his patient a service of the very best. But it has clearly become impossible for every general practitioner to take this attitude or give this service, and many would be thankful if they were no longer expected to practise what they regard as a specialty. Moreover, those who do in fact want to do such work might welcome the withdrawal of unenthusiastic competitors. Be this as it may, what is immediately to be expected is that the Ministry will instruct each local authority to consult with the medical profession in its district and prepare a panel of those practitioners who are best qualified to assist midwives in case of need. From this no great flight of imagination is required to foresee a day when post-graduate diplomas will be demanded as a condition of obstetric practice, and the Ministry's present report marks a turning-point which it is well at least to recognise.

THE VOLUNTARY HOSPITALS GOODWILL AND FINANCE

THE recommendations of the commission on the voluntary hospitals summarised on p 1123 deserve careful study. The commissioners show a full understanding of the spirit that inspires the traditional system of hospital administration in this country and the value of the freedom associated with voluntary service. But they have reached the deliberate conclusion that a limitation of independence is essential to the continued existence and expansion of voluntary hospitals and that methods must be devised whereby co-operation among the voluntary hospitals themselves and between voluntary and municipal hospitals can be promoted. An important recommendation designed to this end is the division of the whole country into separate regions based on the present regional organisation of the British Hospitals Association. The regional councils appointed to co-ordinate the services rendered would have no coercive or compulsory powers but would receive day-to-day information about empty beds and so facilitate the admission of patients. The functions of regional councils would include also the maintenance and direction of an ambulance service, the arrangement for the transfer of patients no longer acutely ill to 'auxiliary hospitals' and perhaps most importantly the strengthening of the hospitals' finances. Following logically enough the general conclusion that if the total annual income of the voluntary hospitals could be distributed in accordance with their individual needs their financial position would not be unsatisfactory it is suggested that in course of time regional funds should be created on lines similar to that of King Edward's Hospital Fund for London. The idea is that such funds would create new sources of support and that the education of donors to contribute to hospitals as a whole would ensure a better allocation of their contributions than results at present from gifts to the particular institution of their choice. If the regional councils acquired enough influence they would be able to improve or close down inadequate and inefficient institutions; new hospitals would not be built nor would old ones be extended without their approval. And the anomalies whereby there is overlapping of effort in one district while others have a defective hospital service would be gradually eliminated.

The question arises whether the voluntary hospital income can be spread over the voluntary hospital system without substantial diminution of the total sum available. It may be that some of those hospitals which are in a better financial position than others are earning it by the value of their work and it may be that some at least of those in financial stress could gain more support if the value of the service they offer to their public were greater. It is curious that in a report which touches on almost every aspect of hospital activity and in remarkable detail there is little reference to variation in the quality of the service given in different voluntary hospitals. The fact that for

the most part this service is of a very high order should not blind us to a second fact that almost everywhere it is capable of improvement, and in some places of considerable improvement. The word service is used in its broadest connotation to include not only medicines and surgery and nursing food and lodging light and air it includes also contact of patients with resident staff and honorary staff, contact of relations with both and with sisters of wards and contact of hospital doctors with general practitioners, conditions of admission and discharge of patients and of consultations for out-patients and finally the proportions in which zeal and discretion are mingled in the almoners and secretaries' departments. It must be obvious to everyone that quality of service is not the only factor in determining support if only because it is so difficult for the laity to discriminate between its grades. Other factors include location, prosperity of the district and the luck which sometimes brings rich patrons to charities irrespective of their special needs. The commissioners themselves point out that the public are not yet educated to give as readily to a hospital service as to a particular hospital. Will they ever be? Certainly now and perhaps always there are many who would sooner give one pound to a poor person who is ill than a pound or some thing less to the sick poor. Local patriotism is a strong incentive to personal service. Anything which weakens interest in the local hospital for its own sake will go far to undermine the present strength of the voluntary hospital system and a so-called parochial interest may well bring stronger financial support to the voluntary system than a regional or cosmopolitan attitude.

If we remain less hopeful than the commissioners that their solutions are necessarily the best ones we must commend their laborious study of the problem. Though the conclusions they have reached are simply and even dogmatically stated, it is obvious that the considerations on which these conclusions are based have been carefully weighed, and that this report will take a worthy place in the series of documents issued during the last 20 years on different aspects of the services and responsibilities of voluntary hospitals. The peculiar merit to which attention is drawn in its pages is that it is a drive towards reform not from without but from within and that for this reason if for no other it is the more likely to be implemented.

THE FUTURE OF TUBERCULOSIS

Dr D ARCY HART'S Milroy lectures concluded in our present issue illustrate the change in attitude that is coming over younger physicians. The facts on which he builds his argument are for the most part widely known. We are most of us aware that there has been an ominous lag in the decline of tubercle mortality among young adults, especially females and especially in depressed areas. Despite the distribution of diagnostic centres throughout the country in the form of tuberculosis dispensaries the proportion of cases

diagnosed early has shown little increase in the last twenty or thirty years. The prognosis per group has also been little affected, the one great therapeutic advance, collapse therapy, is applicable only to a small proportion of cases (10 per cent in the recent London County Council series) although many advanced cases must have passed through a stage, before diagnosis, when it might have altered the course of their lives.

Hence it is evident that, however gratifying the drop in the general incidence of tuberculosis, there is still a long way to go. Delay by the patient in seeking advice is obviously the cause of much late diagnosis, and social factors such as fear of unemployment play a part in causing this delay. Progressive public health authorities are encouraging patients to present themselves for dispensary examination as soon as suggestive symptoms appear, and by facilitating the use of X rays they are ensuring that the examination will be as effective as possible in detecting disease even in its earliest clinical stages. But it is here that Dr HART steps in with arguments which cut at the roots of the present organisation, however efficiently run. He points out that radiological signs appear considerably in advance of symptoms and that this being so it is illogical, in attempting to ensure early diagnosis, to wait for the patient to take the initiative after the appearance of symptoms. The alternative, he suggests, is the periodic health examination of selected groups of people, especially young adults. This examination would be based primarily on radiography, although in groups with low tuberculosis incidence, expense might be saved by preliminary Mantoux testing. This scheme is theoretically no more revolutionary than the periodical inspection of the teeth of school-children, but progress along the lines suggested would lead eventually to "a comprehensive health service that would include the detection of pulmonary tuberculosis as merely one of its important functions." Objections would no doubt be many and varied. At Dr HART's estimate the cost of the tuberculosis scheme, which is at present rather over two shillings per head, would increase and require the expenditure of at least double this amount on diagnosis alone. Other objections include the danger of inducing a tuberculosis phobia and also the difficulty of persuading a symptomless patient to accept the stigma of sanatorium treatment. Although presumably this stigma would diminish if really early diagnosis and treatment were to make complete recovery the rule, the physicians administering such a scheme would have difficulty in inducing a symptomless patient to undergo a course of treatment if it involved the risk of losing his job. Their task would be made still more onerous by their knowledge that many such cases recover without ever knowing they have been ill.

Nevertheless the conclusion to be drawn from Dr HART's lectures is that although it has many excellent features our present tuberculosis scheme does not strike sufficiently near the root of the problem to satisfy the demands of the future. The radical attitude he represents is associated,

moreover, with a growing realisation that preventive medicine cannot make much headway in face of bad social conditions. At present it is all too clear that barely adequate nutrition is often the lot both of the tuberculous patient and of other members of his family just at a time when abundant food is essential to their well being. And those who follow Dr HART's close reasoning must conclude that, if common sense is to be applied to tuberculosis, society must do more to tip the balance in favour of the patient rather than in favour of the tubercle bacillus.

THE SITUATION IN SPAIN

MUCH is said nowadays about the way in which rapid communications have diminished distances. Yet the civil war in Spain is still so far away as to be barely credible. The feeling that these events are only newspaper stories must be the chief explanation of our comparative failure to respond to the desperate needs of people living only a few days' sail to southward of us. In the past week or two something has been done to bring home the realities of the situation in the Basque provinces. Serious attempts are being made to remove from Bilbao women and children whose danger is evident from the fate of Guernica, and we understand that money for this purpose will be gratefully received by the National Joint Committee for Spanish Relief, 35, Marsham street, London, S W 1. Associated with the committee in its general work in Spain are the Save the Children Fund (20, Gordon square W C 1) and the Friends' Service Council (Friends House, Euston road, N W 1), both of which, despite deficient funds, are doing much to dispel the idea that the English have ceased to care.

An illustrated pamphlet called "Children in Spain To-day" reaches us from the Committee Against Malnutrition, with a foreword signed, among others, by Dame Janet Campbell, Miss Harriette Chick, and Miss Edith Pye. It shows that already in January the number of refugees in the Government area exceeded a million, or 10 per cent of the population, and it adds that "the public conscience in western countries may have to prepare itself for a great relief effort in the near future, if the misery of a famine upon our European continent—however short its duration and restricted its scope—is not to be repented in our time." There is no collapse of health and welfare services, however, on the Government side of the lines, indeed they have expanded remarkably. Hence whatever help is given for the prevention or relief of distress is likely to be used effectively.

Finally—which directly concerns the medical profession and its allies—there is a constant demand for medical and surgical equipment and supplies. The goodwill of manufacturers is now being asked for a scheme by which workpeople engaged in making such things may work overtime and thus earn credit with their employers for organisations sending aid to Spain. It is believed that a large proportion of employees would gladly give a few hours a week to such voluntary work, and since the firms concerned would secure the orders for equipment they would gain rather than lose by according the facilities asked for. We hope that many firms may be willing to give the scheme sympathetic consideration. It is planned by Voluntary Industrial Aid for Spain (32, Great Ormond street, W C 1), which is already applying the principle to the manufacture of motor cycle sidecar ambulances. These have proved their worth in mountainous regions where other vehicles cannot reach the wounded.

ANNOTATIONS

ARTHROGRAPHY IN CONGENITAL DISLOCATION OF THE HIP

DIFFICULTIES in treatment of congenital dislocation of the hip joint are due as much to peculiarities in the shape and attachments of the capsule as to misshape of the femoral head. Jacques Leveuf and Pierre Bertrand¹ claim that arthrography provides a valuable aid in assessing the chances of success of closed reduction. The shadow picture obtained in congenital hip disease defines the capsular cavity as consisting of two parts: a cephalic, in relation to the femoral head and the dorsum illi and an acetabular. The communication between the two parts may (1) be free (2) a narrow isthmus, and (3) obliterated by adhesions. In the first group reduction is likely to be easy and retention of the hip in the reduced position may present little difficulty. When communication between the two parts of the capsular cavity is evidently much narrowed Leveuf and Bertrand regard reduction by manipulation as a very traumatic procedure liable to cause damage and not worth attempting; open reduction is then indicated. Arthrography also explains the unsatisfactory clinical results sometimes obtained in cases where the radiographic report on the reduction has been encouraging. Adhesions to the dorsum illi prevent the capsule from slipping down with the femoral head. The arthrograph may show a fold of capsule intervening between the joint surfaces and such a joint will necessarily be unstable.

A variety of substances have been suggested as suitable for injection into joints. Of these Leveuf and Bertrand prefer two—Diagnorenol in a 35 per cent solution and Ténébryl in a 30 per cent solution. Some authors have suggested preliminary injection of a small quantity of air but Leveuf and Bertrand have found this unnecessary. The procedure is however distinctly painful, and general anaesthesia is usually advisable in young children. In others 2 c.cm. of novocain are injected before the contrast solution by means of a 10 c.cm. syringe and a lumbar puncture needle. The hip to be injected is raised on a cushion and the limb held by an assistant who rotates it as necessary. The needle is entered flush with the anterior surface of the great trochanter just below its summit. It is pushed along the neck of the femur till stopped by the projection of the head. When the head is obviously anteverted it may be simpler to aim directly at the head of the bone and not to use the trochanter and the neck as a guide to it. The contrast solution is injected five minutes after the novocain. About 10 c.cm. is usually necessary for a luxated hip although in a normal joint 2 c.cm. is sufficient. The radiogram is taken as soon as possible for absorption of the solution is very rapid and after 15 minutes no shadow may be obtained. A slight circumduction of the joint aids spread of the solution. Where a complete block occurs between the capsular and acetabular parts of the capsular cavity the solution will remain localised around the head. Constriction of the capsule between the acetabular rim and the psoas muscle, its contraction by adhesions or its obstruction by the round ligament produces the narrowing of the isthmus mentioned above. The longer the condition has existed the more definite the capsular deformities are likely to be. This corresponds with the recognised difficulties in reduction in

children seen after the first two or three years of age. A complete and stable reduction will show a crescentic shadow out-lining the head of the bone and without extension on to the dorsum illi.

THE ERADICATION OF OPHTHALMIA

THE Elizabethan poor law broke down badly with the poverty that prevailed in England after the Napoleonic wars. Pauperisation of large masses of people threatened to become the established principle in the running of industry and particularly of agriculture for such monetary grants as were received in outdoor relief tended to be taken by employers as part of the wages of their employees; indeed some farmers made it their practice only to employ those who were on relief. In an attempt to break this vicious circle the Poor Law Act of 1834 was introduced with its radical change of emphasis from outdoor to indoor relief. Under the new dispensation whole families were transferred to the workhouses and care was taken not to make these comfortable. The inmates were herded together—the old and the young, the sick and the healthy, the desperate and the merely squalid. What it all meant in terms of human misery may be guessed from the columns of this journal at the middle of last century: the example reproduced on p. 1145 is sufficiently shocking. And readers may remember *Oliver Twist* or the *Parish Boy's Progress* which appeared in 1837.

Not the least of the problems that emerged was the wholesale infection of children at workhouses with trachoma and gonorrhoeal ophthalmia. The difficulties did not lessen to any extent when poor law schools came to be built to replace the private contractors' schools which the guardians used at first because they were cheapest. When the poor law schools ultimately did come in the fifties no provision was made for more than the most elementary treatment of the sick child. These institutions which later came to be known as barrack schools, were almost ideally planned for the propagation of infective conditions among the very large number of children herded in them and the spread of ophthalmia was but part of the larger problem of the spread of infectious diseases in general. The guardians were not altogether oblivious to their duties when an epidemic broke out costly steps were taken to check it. But a feature of these epidemics was the advice given with monotonous frequency by every ophthalmologist called in and declined with equally monotonous persistence by the guardians—the establishment of sufficient facilities to isolate every infected child within the schools or better still in some central outside institution where they could be kept under school conditions until every sign of infection had disappeared. A tentative experiment by Nettleship in 1873 fully justified such a procedure but the cost of erecting such a central hospital school was considered a final objection just as the cost of erecting schools under the authority of the guardians in tend of sending children to the contractors' establishment had been held as an equally final objection a generation earlier. In the meantime the toll of complete or partial blindness kept on mounting steadily in the good years fleetingly in the bad years. No poor law school was ever completely free from ophthalmia and in some almost all the children were affected. Persistent agitation against this state of affairs ultimately led to the setting up in 1891 of a departmental committee to investigate the whole

¹ *Pr Med* March 29th 1937 p. 457

working of the Poor Law Act as it affected children. The labours of that committee led to a complete change in poor law education and a central ophthalmic isolation hospital school came at last to be built when the Metropolitan Asylums Board was charged with the responsibility of looking after the physically defective children in poor law schools. The central hospital school, White Oak Hospital, Swanley, was opened in 1903, and a year later the sister institution, Highwood Hospital at Brentwood. Trachoma quickly ceased to be a problem of importance as against 292 cases admitted in 1903, 10 were admitted last year, despite the fact that the hospital draws nowadays not only on what is left of the poor law school services, but also on the whole of the elementary schools under the London County Council. Indeed, trachoma was stamped out with surprising ease once the proper machinery was established, and White Oak Hospital is no longer a school devoted exclusively or mainly to trachoma, but has become a highly specialised institute for dealing with chronic eye diseases in children.

The lesson that Mr Arnold Sorsby emphasises in his review of the origin and development of White Oak Hospital,¹ which he serves as visiting ophthalmologist, is the one to which the Board of Education drew attention in 1929—namely, that there is still a dead weight of external eye conditions in children all over the country. It must be admitted that London, with its rate of 4.9 per 1000 as against 14.7 for the country as a whole, has reason to be satisfied with the achievement of its hospital school institution, and it is regrettable that there is only one such institution in the whole of the country. The change in the character of White Oak Hospital leaves one wondering not so much that the problem which the hospital has solved was ever allowed to arise, but that the road to its eradication should have been so full of difficulties and obstruction. Like most successful public health measures, the history of the hospital illustrates not so much the "inevitability of gradualness" as the desperate gradualness of the inevitable.

ABNORMALITIES OF SWEATING

ABNORMALITIES of sweating may be the result of interference in the nervous supply, of alteration in the sweat glands themselves, or, as in the case recently quoted by Berkman and Horton, at a staff meeting of the Mayo Clinic,² of hysteria. Several cases have been quoted by Wilson³ and another by Uprus, Gaylor, and Carmichael,⁴ in which excessive sweating has occurred on certain parts of the face in association with salivation, when the normal sympathetic nervous supply has been interfered with as a result of previous trauma. Cases of auriculo temporal syndrome and "crocodile tears" show phenomena of a similar type. Wilson suggests that the condition is caused by a hyperactive state of the sweat glands, as the result of removal of inhibition resulting from the degeneration of their sympathetic nerve supply. In the case presented by Mogens Fog⁵ the lesion was one of the glands. His patient, following a prolonged attack of paratyphoid fever, was unable to sweat when exposed to great heat, or after prolonged muscular exercise, such as would produce profuse sweating in a normal individual. He complained of intense discomfort, palpitation, and burn-

ing and flushing of his skin, particularly of his face. Microscopic examination of his skin showed considerable destruction of his sweat glands. Mogens Fog suggests that these phenomena are the result of the body's attempt to promote heat loss by radiation by extreme dilatation of the skin vessels, in the absence of the usual elimination by sweat formation and evaporation. The most interesting feature of Berkman and Horton's case of hysteria associated with absence of sweating is the unconscious resistance on the part of the patient to any muscular effort which might cause a rise in body temperature and so promote sweating, when the nature of her disorder was explained to the patient and this resistance was overcome normal sweating resulted. Uprus, Gaylor, and Carmichael were of the opinion that the immersion method of warming the subject was a more certain and satisfactory method of raising the blood temperature and promoting sweating than the dry air-bath method used by Berkman and Horton. The latter point out that their patient, although showing, in their opinion, signs of sympathetic dysfunction, did not present the usual features of heat allergy, such as the urticaria usually complained of, and they do not mention any history of intense flushing or of dry scaly skin, which were both such marked features in Mogens Fog's case. It is unfortunate that they were not able to test any of the other systems under sympathetic nervous control.

PSITTACOSIS

In 1929 the Minister of Health issued a memorandum calling attention to the existence of psittacosis in England both in birds and in man, and asking that material from suspected cases should be sent to the laboratory of the Ministry for investigation. A new report has now been issued¹ in which the methods for the laboratory diagnosis of the disease are described in such detail that with its aid it ought to be possible to investigate cases of psittacosis in any properly equipped bacteriological department. The Ministry obviously now consider that diagnostic methods have reached a state when they can be relied on for routine use. The new report describes the precautions necessary in handling infectious material and stresses the risks of infection from experimental material. The morbid anatomy of the disease in infected birds is described. Findings suggestive of psittacosis are (1) fibrinous pericardial effusion, (2) greatly enlarged spleen, sometimes with necrotic nodules, and (3) a pale or yellow liver with necrotic or hæmorrhagic spots. It is recommended that direct smears should be made from obviously affected organs and from the lungs and heart blood. The smears are stained with Gramsa or by Bedson and Bland's or Lépine's modification of Castellónada's method. If the smears are clearly positive for virus bodies no further procedures are necessary in routine diagnosis. If they are negative or doubtful the ground up tissues are injected intraperitoneally into mice. Mice injected with virulent material usually die in 5 to 30 days. The post-mortem appearances vary somewhat according to the time taken by the mice to die. If death takes place three or more days after injection the peritoneal exudate is thick and fibrinous and virus bodies can generally be demonstrated in the macrophage cells of the exudate. In man the sputum, blood, and pleural exudate from the living patient, particularly during the early stages of the disease, or such post mortem material

as the spleen affected lung &c should be examined both directly and after passage through mice. In all psittacosis infection whether of birds, rodents, or man the essential change is the invasion and destruction of the reticulo-endothelial cells, and special attention should therefore be given to these cells in the search for virus bodies. A good coloured plate shows the characteristic appearances of these bodies. The concluding paragraphs of the report discuss the special problem of psittacosis in budgerigars (love-birds). The disease in these birds is less severe than in ordinary parrots and parakeets and instead of dying they may survive to become carriers of the virus. Further investigation is required as to the extent of infection among the budgerigar flocks of this country and the Ministry asks pathologists to endeavour to obtain more information on the matter.

SÉRUM TREATMENT OF PNEUMONIA

THE treatment of lobar pneumonia with specific antibacterial sera began in America soon after the discovery of the serological types of the pneumococcus in 1913 and later it received a decided fillip from Felton's discovery of a practical process for the refinement and concentration of antisera to Types I and II pneumococci. Following the good reports of Cole Park, Bullowa Cecil, Finland and others several of the United States, notably Massachusetts and New York have begun a pneumonia service to encourage the serum treatment of lobar pneumonia in smaller urban and rural districts—a plan which may be recommended especially to the industrial areas in the midlands and north of England and to Scotland where pneumonia is more common than it is in the south. Meanwhile the pioneers forgo ahead. The division of the heterogeneous Group IV pneumococci into some 20 specific types by Cooper and her co-workers has enabled the clinician to find out the relative incidences of these types as causal organisms of lobar pneumonia and the serologist to prepare antisera to the more common of them. In particular the treatment of lobar pneumonia due to Types V VII VIII and XIV pneumococci has been under investigation. For example Bullowa and Wilcox¹ have collected 249 cases of Type V lobar pneumonia (or 7.5 per cent. of the total pneumonias) at the Harlem Hospital, New York in the past seven years in comparison with a mortality rate of 20.8 per cent. in an untreated series of 163 there were only 5 deaths (7.5 per cent.) among 67 treated with serum. Similarly Finland and co-workers,² at the City Hospital, Boston isolated Type VII pneumococci from 195 patients in seven years, representing 5.5 per cent. of all the cases from which specifically typed pneumococci were obtained during this period. Of these 195 were suffering from pneumonia and it is significant that whereas Type I and II infections are almost constantly lobar in type about one fifth of the Type VII cases were classified as broncho-pneumonia. In a series of 30 cases of Type VII lobar pneumonia rapid and permanent clinical improvement followed treatment with concentrated type-specific antiserum. Finland and Tilghman³ have reported similar results in a small series of Type V lobar pneumonia. Nor in the pursuit of new types has Type I been forgotten as may be seen from the paper⁴ Cecil read to the International Micro-

biological Congress last summer. The illness he says from being a serious exhausting infection of 7-8 days duration can be reduced by early serum treatment almost to the status of an influenzal attack. In other words it is dramatically aborted. Spread of infection is prevented bacteriemia is checked complications are inhibited and the death rate is cut to approximately one-sixth of the standard mortality for Type I pneumonia. Meanwhile despite the truth of Cecil's remark that reports on serotherapy of lobar pneumonia have been without exception favourable little enthusiasm for this new line of treatment is being shown in this country. We were glad therefore to be able to publish a few weeks ago the observations made by Drs. Langley Mackay and Stent⁵ on Types I and II pneumococcal pneumonias treated with specific sera at the Hope Hospital Salford. Though some of their conclusions are open to argument it is clear that the work they are doing is of real value.

THE SEX HORMONES IN ECLAMPSIA

THE work of O. W. Smith and G. Van S. Smith on the secretion of sex hormones in eclampsia and pre-eclampsia has already been annotated in these columns.⁶ These authors reported that the blood urine and placentas of eclamptic subjects contained excessive amounts of a gonadotropic hormone and less constantly a paucity of oestrogenic hormones. Their experimental results indicated that the extra gonadotropic hormone was the same luteinising type (prolan B) that is found in normal pregnancy; and that it was derived from the placenta. The methods at present available for the assay of sex hormones are far from satisfactory but if the above observations are correct it becomes important to find out whether over-secretion of prolan B is responsible partly or wholly for eclampsia or whether it is merely a secondary response to some other dislocation of endocrine balance—analogue for instance to the excessive output of prolan A which is seen at the menopause.

With an equation involving so many inter-related variables as the reproductive cycle it is no easy task to distinguish between cause and effect. The fact that toxæmia is especially common in multiple pregnancy and in cases of hydatidiform mole suggests that increased secretion of prolan B may be of primary rather than secondary import. But the inference is not conclusive and it is more to the point to ask whether when eclampsia complicates an otherwise normal pregnancy hypersecretion of prolan precedes or merely accompanies the clinical symptoms. Preliminary observations by Smith and Smith suggested that over-secretion may antedate symptoms by several weeks and they now⁷ bring forward further evidence that bears out this suggestion. They have collected serial samples of blood and urine throughout pregnancy in a series of 27 pregnant women and estimated the prolan and oestrin content of the samples. Their series includes 11 diabetic subjects, who were selected because the incidence of toxæmia is high in diabetes. Of their 27 patients, 6 developed pre-eclampsia, 4 of these being diabetics, 17 including 5 diabetics remained free from symptoms while the remaining 4 pregnancies were neither normal nor frankly toxæmic. In the toxæmic patients high prolan and low oestrin figures were observed and it seems clear that the rise in serum

prolan occurs about six weeks before the appearance of clinical symptoms

This strengthens the opinion that over production of prolan plays some part in causing eclampsia. How it does so is uncertain. There appears to be a reciprocal relationship between the prolan B and oestrin content of the plasma, and oestrin deficiency may be the important factor. It does not seem likely that over-secretion of prolan is the only cause of toxæmia, for eclamptic symptoms may be wholly lacking in cases of chorion carcinoma, where the output of prolan is enormous. The work of Smith and Smith has not, therefore, solved the problem of eclampsia, but one may hope that further research along these lines may eventually disclose the secret, and lead to rational, instead of empirical, treatment of these tragic illnesses.

LONDON STARLINGS

It has been shown that the genitalia of many birds, mammals, reptiles, amphibians, and fish may be induced to anticipate their normal time of development by extending the daylight available in winter and early spring by artificial illumination, lengthening daylight seems certainly to be an important factor in spring breeding, and it is possible that man had a more definite reproductive reason than he has now before he learned to equalise his days with artificial light. There is also some evidence, not altogether consistent, that maturation may be hurried by disturbance and curtailing the usual hours of sleep. Prof. William Rowan now finds¹ that the testes and ovaries of starlings from the huge flocks which come into London every night to roost are more forward in development than those of country birds, and suggests that this is due to their being kept on the fidget by the noise of traffic, the light at the roosting places he finds to be well below the effective threshold. The night noises of London are indeed dreadful, but we doubt whether he has made out his case. Birds often choose to put their nests in noisy places by railway lines and busy high roads, so that it is unlikely that they find such conditions disturbing. Prof. Rowan also does not state the origin of his country controls, whether they came from a big country roost or from sporadic birds. The former is obviously necessary since the dormitories in woods and plantations far from towns are by no means altogether quiet at night. Perhaps it is not the noise of the vehicles but the aggregation of so many birds together that stimulates sex.

DIVINYL ETHER

WHATEVER may be its merits or demerits as an anæsthetic for long operations divinyl ether is certainly a most valuable agent when a short but profound narcosis is required. It is not uncomfortable or irritating to inhale, and the patient recovers quickly and generally without distress from its effects. Moreover, it has the great practical advantage that it can be administered by very simple means. These and other points are well brought out in a recent review of a series of 2675 administrations.² The authors recommend that when more than half an hour's anæsthesia is wanted the ether should be volatilised with oxygen, otherwise they use a simple drop method on a few layers of loosely fluffed gauze. Divinyl ether is of course a potent anæsthetic, the

concentration necessary in the blood for production of anæsthesia being even less than that of chloroform. Consequently the drug must be given with due care, and danger is easily introduced if a closed apparatus is employed by means of which too high a percentage of vapour would be rapidly acquired. The wide applicability of divinyl ether is illustrated by the fact that in this series the youngest patient was fifteen months old and the eldest seventy-five years. The authors remark on the freedom from post-anæsthetic pulmonary complications. Thus, however, would surely be expected from any anæsthetic used for such short periods of time as was divinyl ether on most of the recorded occasions. It is three years since Wesley Bourne of Montreal³ recorded his satisfaction with divinyl ether in obstetrics, and we would be interested to learn whether it has been tried for that purpose in this country. So simple a method if it proved equally safe might well come to rival gas and oxygen in popularity.

THE MARCH OF TIME

MANY of our readers may not know, but their children will tell them, that this is the title of an instructional—or, as it is called technically, a documentary—film which is shown in many picture theatres as a serial. In this film, which consists of several short episodes, the moving picture is used as a newspaper or rather as a magazine. Accompanied by a running commentary it depicts matters of current interest, grave and gay, and it is changed every few weeks. One cannot see some of the episodes dealing with a serious subject without being impressed by the extraordinary, even alarming, power of this new technique in educating and moulding public opinion. The latest edition of this series—No 11—contains an episode entitled *The Conquest of Cancer*. The greater part of the film has been made in the United States. Several of the leading American medical authorities on cancer appear, without their names being mentioned, and make brief statements emphasising the fact that cancer is curable, and that many thousands of persons have been cured of cancer because they have sought medical advice sufficiently early. They warn the public against the use of quack cures on which in the United States a large amount of money is being wasted. The scene then shifts to England where Sir Kingsley Wood appears on the film to teach the same lesson. The film has evidently been editorially supervised by responsible medical authorities in America, and it proves that the admittedly difficult task of educating public opinion with regard to cancer can be accomplished effectively and at the same time with tact and restraint. The English portion is not as strictly anonymous as the American, and though no exception can be taken to the discreet reference to distinguished workers made by Sir Kingsley Wood, danger lies in this use of the cinema to advertise individual institutions. It must not be allowed to weaken the self-denying code of anonymity that the medical profession has for very good reasons imposed upon itself.

WE regret to learn of the death at an advanced age of Prof. Bennett May, emeritus professor of surgery at the University of Birmingham.

Queen Mary has appointed Mr C. B. Goulden, surgeon oculist, and Mr Francis Donovan, surgeon dentist, to her household.

SPECIAL ARTICLES

BRITISH HOSPITALS ASSOCIATION
REPORT OF A COMMISSION ON VOLUNTARY
HOSPITALS

THE annual conference of the British Hospitals Association appointed on June 1st, 1935 a commission to take into consideration the present position of the voluntary hospitals of the country to inquire whether in view of recent legislative and social developments it is desirable that any steps should be taken to promote their interests, develop their policy and safeguard their future, and to frame such recommendations as may be thought expedient and acceptable. The members of the Commission were Viscount Sankoy (chairman) Alderman Miss Bartleet Sir Henry Brackenbury M.D. Alderman Alan Davies, Prof. L. S. Dudgeon F.R.C.P. Mr H. L. H. Hill Col D. J. Mackintosh, M.B. Mrs E. M. Munson S.R.N. Sir Reginald Poole Provost A. W. Sheen M.S. with Mr R. H. P. Orde as honorary secretary.

After taking a large body of oral and written evidence from representatives of all the associations which could give valuable information, the Commission have issued their report.¹

The Commission recall the action of the Minister of Health in 1921 in setting up the Cave Committee to consider the present financial position of the voluntary hospitals and to make recommendations as to any action which should be taken to assist them. The Cave Committee reported that the lack of organisation and co-operation among the voluntary hospitals detracted from their efficiency and caused much avoidable expenditure. These institutions which should be parts of a connected system were for the most part units working in isolation or in competition with one another and learning little or nothing from one another's successes or failures. Subject to qualifications concerning the teaching hospitals and special hospitals the committee saw no reason why arrangements should not be made both for defining the functions of hospitals and for promoting co-operation among them. They accordingly recommended the setting up of a Voluntary Hospitals Commission consisting of up to twelve members nominated by the Minister of Health the Secretary of State for Scotland the Joint Committee of the British Red Cross and the Order of St. John of Jerusalem King Edwards Hospital Fund for London the British Hospitals Association the Royal College of Physicians, the Royal College of Surgeons the British Medical Association and the Scottish Committee of the British Medical Association also the formation of local voluntary hospital committees nominated by the Lord Lieutenants. They hoped that although these bodies were to be established primarily for the purpose of distributing definite sums of money they would continue to perform their functions after these sums had been exhausted to collect information advise on accounts marshal appeals for funds, act as clearing houses for patients and promote the grading and co-operation of hospitals in their areas. They were to have no compulsory powers but would derive authority from their personnel and from their control over the distribution of money grants. Both the commission and the local committees were set up and distributed

£500 000 which had been granted them by Parliament. They survived for some time after this money had been spent but failed to bring about the reforms which the Cave Committee had urged as necessary for the efficiency of the voluntary system. They gradually disappeared—according to the present Commission—because possibly owing to their method of appointment they never secured the whole-hearted support of the hospitals also because in 1921 the efficiency of the voluntary hospitals as a system and not their individual existence was at stake because opinions as to reform differed and because there was no external menace to drive them together. The stimulus of immediate danger to their existence which was absent in 1921 has now the Commission say been supplied by the passing of the Local Government Act 1929 and the advent of the council hospital. To day the voluntary hospitals are themselves demanding those very reforms which the Cave Committee urged upon them and which they neglected to carry out.

THE COMMISSION'S RECOMMENDATIONS

This is the thesis on which the present Commission base their recommendations of which the principal ones are as follows:—

- 1 The division of the country into hospital regions
- 2 The formation in each region of a Voluntary Hospitals Regional Council to correlate hospital work and needs in the region
- 3 The formation of a Voluntary Hospitals Central Council to co-ordinate the work of the regional councils.
- 4 The establishment of central and regional offices
- 5 The initiation of the above scheme by the British Hospitals Association with the subsequent incorporation of the scheme in the work of the association
- 6 The grouping of hospitals in a region round a central hospital
- 7 The grading of hospitals into central, district and cottage hospitals.
- 8 The creation of a regional fund for the benefit of all the hospitals in a region
- 9 The payment of the expenses of the new organisations proposed from hospital and regional funds and from government grants.
- 10 The adoption by all hospitals of a uniform system of accounts
- 11 The securing of financial aid for hospitals from the State and from the local authorities
- 12 The adoption of improved methods for the collection of funds for hospitals.
- 13 The setting up or development to the full in all regions of contributory schemes
- 14 The making of arrangements by which all the hospital beds in a region can be utilised in the best interests of patients and to the fullest extent
- 15 The full provision of auxiliary hospitals to relieve the main hospitals
- 16 The undesirability of the establishment of special hospitals and the affiliation—as far as possible—of those at present existing with general hospitals
- 17 The establishment of machinery to obviate congestion in some hospitals and empty beds in others
- 18 The provision by all hospitals of accommodation for paying patients
- 19 The restriction of attendance at out-patient departments of hospitals by adopting certain limitations and the taking of steps to remedy the present inconvenience of departments
- 20 The making of appointments to the visiting medical staff of a hospital under the guidance of appropriate experts
- 21 The appointment of a member of the visiting medical staff of a hospital to be governed by a formal agreement between such member and the hospital

¹ Published by the British Hospitals Association 12 Crosscourt-crescent London, S.W. 1 1p 23 1s

22 The payment—with certain qualifications—of the visiting medical staff

25 In regard to the nursing service (i) the improvement of the conditions including higher pay for trained nurses, (ii) the adoption of a higher educational standard for entrants, (iii) the commencement of training in all cases by attendance at Preliminary Training Schools, (iv) the recognition of the position of the matron as an administrative officer and her direct access to committees when matters affecting her department are under consideration, (v) the universal adoption of a pensions scheme

24 The recognition of the special qualifications required for the chief administrative officer of a hospital

25 The furtherance of a definite scheme of education in hospital administration

26 The universal adoption of a pensions scheme for the administrative staff

27 The provision of the services of a qualified accountant for hospital accounting when required

28 The consideration of the advisability of separating the collection of funds from administration

29 The securing of those holding statutory qualifications for some auxiliary services in hospitals and of those specially qualified through a recognised test for certain others

30 The organisation of the ambulance service in a region by the local authorities and the adoption—with certain exceptions—of a moderate charge to the patient for the service

31 The recognition of the special requirements of teaching hospitals

32 The keeping by all hospitals of patients' records on a uniform system of classification, a record department at each regional office

33 The furtherance by hospitals of research and of "follow up" methods

34 The publication by hospitals of annual clinical reports

35 The adoption of suitable publicity methods for hospitals with formation of a press bureau and the publication of a periodical

36 The special organisation of the voluntary hospitals in Scotland

37 The practical recognition by all hospitals of the powers conferred by Section 13 of the Local Government Act, 1929, with full co-operation as regards provision for the public health between voluntary hospitals and local authorities

FINANCE

The Commission conclude that if the thousand British voluntary hospitals could distribute their total annual income according to their individual needs, their financial position would not be unsatisfactory. They suggest as an ideal plan the pooling of a percentage of the revenue of each hospital, but doubt, however, whether the supporters of voluntary hospitals are yet prepared for so fundamental a change. They therefore recommend as a first step the creation of regional funds on a basis similar to that of King Edward's Hospital Fund for London. Such funds would, they think, possess the double advantage of creating new sources of support and of educating donors to help the hospitals as a whole. A uniform system of accounts would be necessary, but the Commission do not recommend the adoption of the "Revised Uniform System" of the King Edward's Fund, believing that a modification of this system could be devised that would strike a balance between the advantage of having good statistical records and that of simplicity. The Commission find no reason why the State should not contribute grants in aid of the voluntary hospitals. They lay down governing principles for contributory schemes, the establishment and growth of which they welcome. They also favour the establishment of provident schemes for paying patients of moderate means. They consider it to be the duty of voluntary hospitals to provide beds for paying patients of all

classes of the community and to give them a free choice of medical attendants, who should receive a separate fee

VISITING MEDICAL STAFFS

The Commission accept the payment of medical staffs as a general principle, but the suggestion was made to them that there exist three classes of medical staff to which this principle does not apply with the same force—viz, the staffs of teaching hospitals, the staffs of hospitals with a considerable number of pay-beds, and the senior staffs of other large general hospitals. They found some point in this contention when applied to the first two classes. A position on the staff of a hospital with a medical school is, they recognise, undoubtedly a valuable asset, but since there must be a lag of a number of years before the teacher can reap the reward of the time and work which he has given, the general argument for some form of payment therefore still applies to the junior members of the staff. If the State ever makes a special grant to teaching hospitals (as was recommended in the Report of the Scottish Departmental Committee on Health Services last year) some portion should, they think, be assigned to those members of the staff who actually give the clinical instruction. Moreover, in hospitals with a considerable number of pay-beds, the patients in which are liable for the fee of their medical attendants by private arrangement, the medical staff stand to gain a material advantage. This, however, only applies when the staff have a monopoly of attendance on patients in the pay beds. The Commission do not see that the senior staffs of other large general hospitals derive advantages which would lessen their claim to payment. Prolonged service on the staff of a hospital sometimes has material value, but by no means always, and it is not always the senior members of the staff who are preferred by their fellow practitioners or by the general public in the district.

While, therefore, the Commission agree with the general principle that the medical and surgical staffs should be paid, they think that there might well be exceptions or modifications in these stated directions. They would not expect a universal application of the principle immediately, because the circumstances of individual hospitals and the attitude of many members of their staffs vary so widely. If the principle is right, however, they think that the formidable difficulties in the way should in time be overcome. They suggest that the most satisfactory method may ultimately be found to be a definite part-time honorarium or salary. This must involve a statement of the duties undertaken and an obligation to fulfil them more exactly than is sometimes considered necessary to day.

THE NURSING SERVICE

Broadly speaking, the recommendations of the Commission for the improvement of the nursing service appear to follow those of THE LANCET Commission on Nursing. The problem of attracting a larger number of good candidates can, the Commission say, only be met by making the conditions of service more attractive. The school leaving certificate may be a suitable standard of education, though it may not be required of some otherwise suitable applicants. All nurses should begin in a preliminary training school, and central schools should be established in regions. From these schools candidates would pass to recognised hospitals. All possible opportunities should be taken for higher training and qualification. The Commission welcome

the diploma in nursing of certain universities and hope that this development will be extended. Special courses—e.g. in housekeeping and dietetics—should be facilitated. Remuneration should they say be higher and all nurses should be enabled to become members of the Federated Superannuation Scheme for nurses and hospital officers. Present hours of duty are considered to be too long the ideal being a 48 hour week. Until this ideal is attainable more nurses should be appointed to the relief staff. The ratio of nurses to beds should be at least one member of the nursing staff employed during every 24 hours to every two available beds, excluding nurses in special departments. Every large hospital should have a suitable nurses home with full amenities. In smaller hospitals separate accommodation should be provided. The ratio of trained nurses to nurses in training should be increased. Small hospitals not recognised as training schools should be staffed by trained nurses with adequate domestic help.

The report contains many other matters of interest notably discussions of the relationship between voluntary and council hospitals and of the out-patient problem.

MATERNAL MORTALITY

THE TWO REPORTS

LAST week we gave a preliminary account of the Ministry of Health's report¹ on maternal mortality. The investigation was made, it will be remembered to discover why the maternal mortality rate of this country has tended to rise while the conditions of living, the health services and expectation of life have improved. In particular the maternal mortality has been persistently greater in some districts than in others: the investigation has therefore been directed to the conditions in those and in a few control districts. It was made by study of the figures in the Registrar General's Review and of others relating to those districts extracted by the General Register Office for the investigation by inquiry into the circumstances of all maternal deaths and abortions in those districts in 1934 and by survey of the maternity services. The local inquiries were made by six medical officers of health three of whom had special knowledge of maternity services and three of health services in general. They were assisted by Sir Comyns Berkeley in a consultant capacity and by the local medical officers.

The districts visited were mainly those which in the decade 1924-33 had experienced an average puerperal mortality rate in excess of the arbitrary figure of 5 per 1000 live births. They included the administrative counties of Lancashire the West Riding Cumberland and Westmorland the 22 county districts autonomous for maternity and child welfare work in the West Riding and 14 in Lancashire the 18 county boroughs of Blackburn Blackpool Bolton Preston Rochdale Wigan Barnsley Bradford Dewsbury Halifax Huddersfield Sheffield Wakefield Canterbury Carlisle Darlington Lincoln and Plymouth. In addition for comparison visits were paid to seven districts where the average mortality rate for the decade had been low. These were the administrative county of Lincoln (Nottingham) and the county boroughs of Barrow Bootle Liverpool Lortsmouth West Ham and Haringpool.

¹ Report on an Investigation into Maternal Mortality. Ministry of Health, Cmd. 5133. London: H.M. Stationery Office, 1937. Pp. 333. 5s. 6d.

THE STATISTICS OF MATERNAL MORTALITY

The trend of the puerperal mortality in England and Wales has been slightly upward during the past ten years (Fig. 1) and the report points out that the changes in classification of deaths have not been such as to affect this conclusion. It is possible that increased accuracy of certification may have contributed but this factor cannot be assessed. A stationary or upward trend is also shown by the mortality rates in other countries and although differences in certification and classification make comparison of little value the international position of England and Wales is probably neither so completely unsatisfactory nor so near the bottom of the list as some allege. Studying the individual causes of death it appears that the rise in the total rate since about 1923 has been due to a definite increase in the rate from sepsis while that from other causes has remained about the same. The mortality from toxæmia shows an upward trend while that from hæmorrhage a decline. The increase over eight years in the rate for total abortions is about 18 per cent as compared with about 9 per cent for all puerperal causes.

Taking the whole of the 70 county boroughs of England no association between overcrowding and puerperal mortality was found. In the West Riding however the towns with most overcrowding tend to have the highest rate of puerperal mortality the three boroughs with the largest proportion of overcrowding having also the highest mortality from toxæmia. In Lancashire on the other hand the towns with most overcrowding had a lower mortality than the others and similar results were obtained for the districts of London.

On the whole the proportion of women employed in any "gainful" occupation and the rates of puerperal mortality are found to rise and fall together when the occupation is industrial the tendency is more conspicuous. In the county boroughs of England the proportion of women employed in personal service tended to be inversely related to mortality rate; thus the report points out does not mean that personal service per se is conducive to a low rate, and the association is reversed in London. The extent of unemployment seemed to be the best index of prevailing economic conditions available for general use and using that index no consistent association is found between puerperal mortality rates and economic conditions either in the same year or the succeeding year. The distribution of rainfall and of the incidence of puerperal mortality are similar (Figs. 2 and 3) but unfortunately the meteorological observations have not necessarily been made in the administrative areas to which the mortality returns relate. The statistically significant degree of correlation which exists does not mean that there is any causal relation between rainfall and puerperal mortality; the association may be merely that high rates and high rainfall occur in certain geographical areas of the country. The report says that there may also be an association between other climatic factors—sunshine temperature and humidity for instance—but the data to demonstrate this association are not available. In the areas visited deaths from puerperal sepsis tend to occur most frequently in the coldest quarter of the year the time succeeding the wettest and moistest quarter, death from toxæmia in contrast tend to occur most in the warmest quarter which succeed the driest and sunniest.

The relation of parity to risks of maternal mortality was studied from a sample of birth. Between

FIG 1 (reproduced from the Ministry of Health Report)—Trend of puerperal mortality in England and Wales during 1911-34 as indicated by a line representing the five year moving averages of the rates

35 and 40 per cent of legitimate and from 60 to 70 per cent of illegitimate live births were the outcome of first pregnancies, and after excluding deaths from abortion about 45 per cent of the deaths of married women are found to occur in first pregnancies. The average risk to married women who have already reached the seventh month of pregnancy is lowest in the third pregnancy and then increases progressively with birth order. The average risk of confinement at the first pregnancy is about 25 per cent in excess of the general risk for all confinements and exceeds the risk for subsequent confinements up to about the eighth, after which the risks become greater than that of a first confinement. Twin confinements are subject to a considerably higher mortality risk than those resulting in a single child. The falling birth rate has resulted during the last ten years in an increase in the proportion of first confinements and, at the same time in a fall in the proportion of confinements of women who have had many children.

The opposing effects of these changes on the total mortality risk have been almost complementary in the country as a whole so that an increase during ten years amounting to round about 1 or 2 per cent of the death rate is all that can be accounted for by fall in fertility. The rates of puerperal mortality among the wives of men classified socially according to their occupations decline in passing from professional and middle classes to the unskilled classes, this being specially evident for puerperal sepsis but not for puerperal hæmorrhage.

In several of the districts visited it was suggested that the prevalence of scarlet fever in the area coincided with prevalence of puerperal fever. On examination of the evidence the prevalence of puerperal sepsis in an individual district did not seem to depend on the prevalence of other diseases of streptococcal origin although for the country as a whole conditions favourable to a high prevalence of puerperal fever seemed to predispose also to a high

FIG 2 (from the Report)—Puerperal mortality by counties during 1924-33. Group A = rates higher than that of England and Wales (i.e. 4.21 per 1000 live births) by 20 per cent or more. Group B = rates higher by less than 20 per cent. Group C = rates lower by less than 20 per cent. Group D = rates lower by 20 per cent. or more.

prevalence of scarlet fever erysipelas and diphtheria (Fig. 4.)

CIRCUMSTANCES OF MATERNAL DEATHS IN 1934 IN THE AREAS VISITED

In all, 775 deaths were investigated, but in 3 pregnancy was found not to be present and in 2 the pregnancy was considered to be incidental to the death. All available data relevant to environmental, social, and economic conditions of the remaining 770 cases and particulars of death were collected. The deaths were classified for the most part with small modification according to the recommendations of the Scottish Departmental Committee.

Toxæmia.—There were 137 deaths directly due to toxæmia of these 73 were attributed to eclampsia. Again the greatest number of deaths was found in the third quarter of the year the financial circumstances of most of the patients excluded the likelihood of poverty and consequent lack of food being the cause. The supervision during the antenatal period was judged to be good in only 2 cases reasonably careful in 12 deficient in 37 none in 11 and unknown in 11. To pre-eclampsia toxæmia 20 deaths were assigned 10 of these occurring in the third quarter. The ages of 12 of the women were between twenty-five and forty and only 1 was over forty. 13 were primiparous. The 6 deaths from pyelitis bore out the statement that pyelitis occurs commonly in young women for 5 of them were pregnant for the first time and all of them were under twenty-nine. Hyperemesis accounted for 10 deaths undefined toxæmia for 7 and acute yellow atrophy of the liver for 6. In no less than 28 per cent. of the 770 deaths investigated toxæmia either influenced the cause or was the cause of death. It is therefore held to be a contributory factor in a large proportion of maternal deaths.

Hæmorrhage.—Antepartum hæmorrhage in which there was no evidence of abnormal implantation of the placenta caused 27 deaths, a large proportion of the women were in the higher age and parity groups; 15 were over thirty-five years old and 16 were mothers of more than four children. In 4 a history of from one to four abortions was obtained. Placenta prævia with hæmorrhage accounted for 25 deaths, again the women were mainly in the later years of child-bearing more than half being over thirty-five; 10 of the women were mothers of more than four children and 3 had had eleven, twelve and fourteen children respectively. Postpartum hæmorrhage was held responsible for 21 deaths. The report states that the records of treatment of these cases of 111 demonstrate the need for adequate coagulative and transfusion services. In six instances the early departure of the attendant after delivery

or after hæmorrhage may have influenced the issue.

Trauma and sudden death.—The 92 deaths in this group were classified into obstetric shock 43 embolism 28 rupture of the uterus 7 extensive tears of cervix vagina or vulva 3 deaths associated with anaesthetics 6 and deaths from paralytic ileus and intestinal obstruction after Cæsarean section 5. Over half of these women were between the ages of thirty and thirty-nine and also over half were primiparous but among the group attributed to shock most of the women were under thirty.

FIG. 4 (modified from the Report).—Graph showing percentage variation from the average rate (England and Wales) for 1924-33. Scarlet fever erysipelas and diphtheria = notifications per 1000 population. Puerperal fever = notifications per 1000 live birth. All septic conditions = deaths per million population.

Puerperal sepsis.—If the 84 deaths attributed to post-abortive sepsis are deducted from the total 303 of this group the remaining 219 represent 28.4 per cent. of the total puerperal mortality. The records of treatment varied considerably. Blood transfusion was stated to have been undertaken in 10 cases, and serum to have been administered in 74 while 17 women were treated by Hobbs's glycerin method. The report says that conclusions could not be drawn about serum treatment as in many cases it was not based on scientific principles; various types of sera were administered including human and serum anti-scarlet serum and polyvalent serum. In a number of instances several kinds of serum were given to one patient. Conditions which may have made septic infection more likely were present in many of the cases classified in this group as normal deliveries. Some of the women were in poor health, 23 had definite signs of toxæmia and in 37 there was laceration of the soft parts. The report discusses several aspects of obstetric practice.

Forceps were used in 140 of the 627 cases of the series reaching the twenty-eighth week; their use was unsuccessful in 27. They were applied for occipito-posterior presentation in 12 cases, breech 6, twins 2, contracted pelvis 7, antepartum hæmorrhage 11, eclampsia 13, toxæmia 4, other illnesses of the mother 10 and signs of fetal distress 1. In 14 instances the only reason given for the use of forceps was primiparity; in 20 the indication given was inertia and prolonged labour. Sepsis was the

cause of death in 43 per cent of these forceps cases

Cæsarean section had been performed in 52 of the 927 cases, earlier attempts to deliver had been made in 11 of these and in 3 several attempts at forceps delivery had been made. In some of the districts visited an obstetric specialist had not been available and surgeons with little obstetric experience had been appointed to act in their stead. They had naturally been inclined to adopt a procedure which was familiar to them, the percentage of deliveries by Cæsarean section at three big London hospitals investigated varied between 0.55 and 3.49, whereas in a hospital with a small maternity unit 27 of the 104 deliveries in a year were by Cæsarean section, while 52 cases were normal.

Condition of the infant—An attempt was made to find out the toll of infant life represented by the maternal deaths, 101 mothers of the series of 770 died undelivered and there were 127 abortions, in all, half of the pregnancies ended in the death of both mother and fetus.

The conclusion is reached in the report that in many instances ignorance or lack of co-operation on the part of the patient or her relatives prejudiced her chance of recovery. The standard of practice of midwives in some cases was considered to be unsatisfactory, the antenatal supervision perfunctory, medical assistance sought too late and procedures inconsistent with competent midwifery were occasionally adopted. The treatment in many hospitals was efficient and comprehensive, in others it left much to be desired. The general practitioner, in a patient's home and faced with problems of great difficulty, often without assistance, in unsuitable surroundings and under unfavourable conditions, many of the histories indicate that notwithstanding the handicaps, careful obstetric procedures were adopted yet sudden and unforeseen complications led to a fatal issue.

After pointing out some of the lessons to be learnt from this series of deaths the report mentions that the conclusions agree with those of the Departmental Committee of 1932, their recommendations have been implemented in the training of medical students, in the development of maternity services, and by the provision of salaried midwives, "but," the report says, "the rôle of the general practitioner in midwifery has not yet received the attention it deserves."

ABORTION

Abortion was investigated by the local inquiries into maternal deaths, by study of national statistics, and by collecting impressions. The report concludes that there does not seem to be any reliable means of estimating the incidence of abortion and that it is difficult and often impossible to differentiate in practice between a spontaneous abortion and one induced artificially. The impression was gained that the practice of artificial abortion is common and appears to be increasing, is more prevalent in some districts than others and is not restricted to any one class. In some areas the provision for in-patient treatment under expert supervision were inadequate. The dangers of artificially induced abortion do not appear to be sufficiently realised and there is urgent need for the education of women about the damage to health and danger to life from attempts to terminate pregnancy artificially. Abortion (whether spontaneous or artificially induced, but excluding cases classed as criminal) is an important factor in the puerperal mortality rate of the country since

approximately 14 per cent of all puerperal deaths are due to this cause. The statistics suggest that the trend of abortion rates is increasing more than that of other puerperal causes. The death rate from abortion is higher in the aggregate of areas with high average mortality rates than that of England and Wales as a whole. There are, of course, many more deaths from abortion among married women than among the unmarried, but abortion is responsible for a greater proportion of the deaths among the latter class and is largely responsible for the higher maternal mortality rate of unmarried women.

MATERNITY SERVICES

The report reviews the evolution of the maternity services up to the present, commenting that at present the local authorities have no say in the selection of practitioners who may be called to the assistance of midwives and to whom they pay fees. The investigators consider that only those practitioners who show special interest in and have considerable practical experience of midwifery should be called to help a midwife, instead of leaving the choice when possible to the patient in accordance with the rules of the Central Midwives Board. Brief reference is made to the excellent results obtained by the Rochdale "experiment" and to other general practitioner schemes.

The investigators suggest that the present provisions for maternity services should be amplified by the establishment, under the direction of the medical officer of health, of a service of obstetric consultants to assist general practitioners and midwives, to conduct consultative antenatal and postnatal clinics, to supervise the treatment of patients in hospitals under local authorities, to investigate the circumstances of each maternal death, and to be responsible for emergency domiciliary treatment by flying squads. They also recommend that more maternity accommodation should be provided with beds for antenatal patients, that antenatal clinics be provided in all but sparsely populated districts where provision for medical domiciliary supervision may be made. Satisfactory arrangements should be made to accommodate patients suffering from puerperal sepsis and abortion. Education of the woman and the general public should be borne in mind to obtain better co-operation, and health visitors should visit homes to encourage women to obtain antenatal care. The investigators also suggest that a service of home helps should be provided where possible and that many necessary extras such as supplementary nourishment, laboratory facilities, and sterile drums of dressings should be available as required.

The Report for Wales

The investigation in Wales was carried out on similar lines and is described in a companion report.² The death rate from childbirth was found to be high in all parts of Wales and for the decade 1924-33 the puerperal mortality was 35 per cent above the rate for England. The rates from sepsis and other causes were high. The rates in the special areas have increased substantially, whereas the aggregate in other areas show a slight decrease. On the whole, where the total death rate was high, the puerperal mortality rate was high too, and the report points out that the non-puerperal death rate in Wales is higher than that in England. It is believed that an

² Report on Maternal Mortality in Wales, Cmd 5193, London: H.M. Stationery Office, 1937. Pp 156. 2s 6d.

excess of intercurrent disease among expecting mothers has been a contributory cause in producing the high rate of anaemia and debility are common.

Doctors now attend fewer confinements than formerly. A good deal of the instrumental delivery by doctors under modern conditions of practice is considered to be unnecessary and is held to have played some part in increasing the maternal mortality. The suggestion is made that more hospital beds should be provided and at them the family doctor should have opportunity of observing the conduct of the case by the specialist in charge.

The maternity services of most of the local authorities are thought to be inadequate and in many parts of the country very little maternity work is undertaken by them. The report calls for extension of the services and attention to the general health and education of the mothers.

EMPIRE CONFERENCE ON THE CARE AND AFTER CARE OF TUBERCULOSIS

At the first session of this conference on May 3rd Lord WILLINGDON took the chair and Sir KINGSLEY WOOD welcomed the delegates on behalf of the Government. Reviewing the position of tuberculosis in England and Wales he said that until ten or eleven years ago tuberculosis stood foremost among the killing diseases in this country. Although the deaths from the disease had fallen conspicuously there was no reason to view the present situation with complacency. The improvement had been brought about by the awakening of the public consciousness to the problem by better preventive measures and better treatment. The occurrence of tuberculosis in an individual sooner or later affected the family resources, and care for the family as well as for the patient played a large part in the treatment of tuberculosis. Papworth village settlement had done much in this connexion.

Sir ARTHUR MACNALLY reviewed the change of outlook on tuberculosis which had taken place both among medical practitioners and the public in the last few decades and referred to recent advances in treatment, diagnosis and prognosis—notably artificial pneumothorax, thoracic surgery, improved radiology and examinations of the blood. The social and economic implications of tuberculosis were far reaching. Sir Penderill Varrier-Jones's work at Papworth was a great contribution but many patients were unfitted temperamentally or in other ways to live in a village settlement; their need for care had been too long neglected but was now receiving more attention from local authorities.

INDIA

Major General Sir CUTHBERT SPRAWSON (India) spoke of the peculiarities of the tuberculosis problem in India. The steady decline in mortality from pulmonary tuberculosis in Great Britain had not been experienced in most overseas countries and certainly not in India. The incidence and mortality of tuberculosis in India were really unknown because the vital statistics except for the Army and the prison population were not trustworthy nor even those relating to the large cities. The public health commissioner had recently estimated that there were about two million tuberculous people in India but this was a very rough estimate comparable to the estimate of one million for leprosy; the speaker

thought the number of cases in India was greater. The vital statistics were likely to understate the numbers because so many cases were undiagnosed and unreported. Even so the cities of Poona and Ahmedabad reported that one death out of every twelve was from tuberculosis and in Calcutta the ratio was even higher. The death rate from pulmonary tuberculosis in Ipswich was 52 per 100,000 population and in Chicago 86 while that for Calcutta the figure was said to be 240 and the real figure was probably even higher. Sir Cuthbert had estimated that some ten years ago one in every seven people in Lucknow died from tuberculosis. At any rate the number of deaths from that cause was certainly very large and there was a general feeling that it was increasing. Twenty years ago Dr Lankester an expert appointed by the Government, had reported to this effect whether the numbers were still increasing was unknown but by analogy with other countries this seemed probable. India was still principally an agricultural country but industrialisation had begun in several areas. Experience in other countries had shown that industrialisation especially if not well controlled, and free immigration of a rural population into city life were accompanied by an increase in the incidence in tuberculosis. The speaker wished to emphasise the magnitude of the danger in India and the pressing urgency of more energetic measures in the campaign.

CANADA

Dr R. E. WOODHOUSE (Canada) said that Canada was greatly influenced in practice and in the general view of the tuberculosis problem by the attitude of her cousins in the United States. Some British modifications of American practice had been made but they had as yet no Papworth. The death rate from tuberculosis in 1936 would be about 60 per 100,000 having fallen to about a third of its height of thirty years ago. The rate among North American Indians was very high about 700 per 100,000 while the rate in other parts of the population was as low as 25. In some areas there was ample accommodation free of charge for anyone with tuberculosis and there was a scheme which gave allowances to wives and creches for the children so that the wives could go out to work. While a man was in hospital the State gave the wife the same pension that she would receive if widowed. If the wife were in hospital an allowance was made to the man for a housekeeper in order to keep the family together. Dr Woodhouse felt that tuberculosis among the North American Indian could be as well controlled as among the whites if there were enough financial assistance.

SOUTH AFRICA

Dr A. D. PRINGLE (Transvaal) speaking on behalf of Dr B. A. Dörmer who was ill explained that the population of S. Africa is preponderantly native the proportions being 2 million Europeans to 7 million natives of whom 6 million are the original tribes of S. Africa. The death rate among natives was certainly alarming and the population was hard to get hold of and to treat, but he did not agree with Sir Cuthbert Sprawson that the statistics of a native population were hopeless or inadequate. In S. Africa the death rate from tuberculosis for the colour population was six times greater than for Europeans. Widely different reports were current about the incidence of tuberculosis in rural areas—a change from the tribal way of life had a profound influence on the health of the natives apart from the effects of mining and urban life.

Prof S LYLE CUMMINS (Wales) said that although the native in South Africa seemed to be very susceptible to tuberculosis the conditions of work played a considerable part in this, the women and children were not so liable to be affected as the men. It was, he thought, impossible for the State at present to finance adequate treatment, and apart from that the natives hated and dreaded being transferred from their home surroundings to marble halls and hospital regulations. A few missionary centres with crude shacks and shelters had achieved much in treating the natives, their workers seemed to have the clue to getting the natives' trust and had been able to treat natives in circumstances which they understood.

At the afternoon session Lord DAWSON OF PENN, who presided, said that the care and after care of the tuberculous claimed attention not only from the humanitarian motive of consideration for the patient but also for the sake of public health. The growth of knowledge and social conscience had preserved many lives which in themselves required every care. He did not think, however, that these patched up lives were good begetters of our future race, unless this aspect of after care were considered a great injustice might be inflicted on the generations to come.

EUROPEANS IN SOUTH AFRICA

Dr A D PRINGLE spoke of the care and after care of the tuberculous among the European mining population of the Rand and among the non mining population of the Transvaal and Natal. His subject, he said, was linked up with the history of the mining industry, which had been in existence for about 50 years. About 1903 it became obvious that a large number of employees were contracting silicotic fibrosis and tuberculosis. The deaths were mainly among men from Cornwall, Northumberland, and Wales. Since those days, four principal institutions to deal with tuberculosis had come into being: first, there was the Springkell Hospital, built by the industry and administered now by a board composed of representatives of the industry and of the Government; second, the South African Institute for Medical Research, also built by the industry. There was the Miners' Phtisis Medical Bureau of Examiners created in 1916 and made up of ten medical men, their job was to examine every applicant for employment in the mines. Every year the bureau examined 20,000 men, of whom some 60 per cent were rejected, they also examined every miner every six months, if a man contracted silicosis he was warned, if he became tuberculous he was no longer allowed to work, and the bureau furnished a report for the compensating board. The fourth institution was the Miners' Compensation Board, consisting of Government nominees except for one representative of the miners. Behind all these was the administrative body of the industry itself, the Gold Mines Production Committee with representatives from each mine. A lump sum was given in compensation to any man who developed silicosis and a man contracting tuberculosis was given a pension which was continued, if need be, to his widow and children, he was offered work on the surface. The sick miner was admitted free of charge to a hospital or sanatorium. Gold mining was, of course, a business proposition like any other and these provisions for the miners cost money, the allowance for compensation this year amounted to about one million pounds. The mortality rate from tuberculosis among miners was now no greater than that in the Royal

Air Force in this country. Of recent years non mining tuberculous patients had been admitted to the Springkell Hospital. Outside the industry there was little provision for such patients.

EFFECT OF CITY ENVIRONMENT

Dr S VERE PEARSON (Mundesley) spoke of the tendency in every country for the rural population to drain into the cities. This change in distribution of population contributed three factors to the problem of tuberculosis: much time and energy was wasted in travelling, recreation in the open air became more and more impossible, and anxiety and worry from the city environment were imposed. The death rate from tuberculosis in the thickly populated areas of Manchester was almost as high as that for Calcutta, while nearby, at the garden city of Wythenshawe, the rate was but one-third of those figures. At Letchworth the rate was lower than those for the counties of Hertford and Norfolk. Comparisons of city and rural communities had to take into account the source from which the city inmates were derived.

Dr F HEAF outlined the main purposes of the London County Council tuberculosis scheme which consisted of three parts: domiciliary, dispensary, and residential. The domiciliary treatment was regarded as the domain of the general and insurance practitioners. The dispensary service was responsible for care, after care, examination of contacts, and special forms of treatment. Residential treatment was now provided free although voluntary subscriptions were accepted. Each area had its own dispensary while the LCC arranged for all resident treatment. This dual control required much co-operation. The after care work of the dispensaries dealt with housing conditions, employment, and education for re-employment. On the whole, provision for post sanatorium patients had been sadly neglected, some boroughs had lectures in handicrafts but these provisions were small in relation to the need. For youths there was a centre at Burrow Hill for training in clerical work and gardening. The after care committee also gave advice and assistance to the patient and his family. Dr Heaf quoted an investigation made in 1926 by Sir Frederick Menzies, in which the death rates from tuberculosis in three London boroughs were compared. Although the rate for all forms of tuberculosis was highest in the poorest borough the ratio of death rates from tuberculosis to that for all causes was the same in each. Environment and social conditions seemed to have no selective effect on the relative mortality from tuberculosis. Although the actual cause of break down in tuberculosis was obscure, infection did not seem to be the chief item. Fatigue and undernourishment probably called for greater attention in a civilised, or mechanised, country. Dr Heaf quoted figures¹ showing that the average rate of incidence of tuberculosis for certain outdoor manual workers in London and the provinces was greater than that for indoor non manual workers. This was a forcible criticism of the old idea that open air was essential in treatment. The class which endured the hardest physical strain, received the lowest wages, and spent the smallest amount on food was the one most prone to tuberculosis. He could not help thinking that the vast majority of adults would remain free from active tuberculosis even if frequently exposed to infection provided they were well nourished.

¹ See *Lancet* 1936, 2 1115

and were not subjected to excessive strain physical or mental. Children on the other hand presented a different problem and demanded protection from the bacillus. Dr Heaf thought it was more important for those responsible for after care to see that the patient and his family had sufficient good food and freedom from worry rather than lay stress on a few stray bacilli.

ENVIRONMENTAL FACTORS IN CARE AND AFTER CARE

SIR PENDRILL VARRIER JONES felt that after care was the most powerful method now available in the prevention of tuberculosis. He wanted the medical profession social workers and those interested in economics to realise that after care must be linked to hospital sanatoriums. He thought the idea of environment had been inadequate. It had so often been taken to include only the material environment. Many patients contracted the disease although they had been working in good conditions the advice that good food and housing and a light job in the open air would solve all problems had to be given up. That raising the standard of living did not necessarily raise the standard of resistance to disease was shown by the present unmistakable rise of incidence of tuberculosis in young women. A definite though undetermined maximum dose of infection was necessary to produce clinical disease and the patient's resistance determined the size of this dose. This power of resistance was governed not only by material conditions and physical exercise but by a mental state. For this reason intensive research should be undertaken into the psychological aspect of the problem without delay. From his observations at Papworth Sir Pendrill was convinced that enforced idleness led to destruction of moral fibre, this aspect had been neglected by medical men who paid too much attention to the lung and too little to the organism in which it was situated. Sir Pendrill was not advocating indiscriminate exercise nor did he believe that work as a therapeutic measure acted by producing auto inoculation. In the treatment of the consumptive the environment had to have something psychological about it. It was curious how few people paused to ask why after-care was necessary. Could it be admitted that it was because we could not cure and in many cases could not permanently arrest tuberculosis? The strange thing was that the longer the case was under treatment and the more elaborate the treatment the greater the need for after-care.

Good housing was essential to enable the disease to be arrested permanently but so were a sense of well being work and a mind free from worry. Work had to be of the right kind for a middle-class or working man had something to sell and which he must sell if he is to have well being of mind. It was disastrous for the man to take on what he considered to be an inferior grade of work or to put him to a job with initiative when he had exercised none before. Many committees imagined that a patient should give his labour to the State but why should he? Labour was his only asset. Too often the medieval outlook was kept that a sick man was inferior. That was not so and frequently the tuberculous were victims of civilisation. The best that could be done for them was to try and compensate for the wrong society had done them by providing the best environment and restoring their working capacity. The result would be cheaper than hospitalisation in cash and morale.

IRELAND

(FROM OUR OWN CORRESPONDENT)

AN EXCLUSIVE POLICY IN NORTHERN IRELAND

A LAWSUIT heard in Belfast last week has drawn attention to regulations made by the Ministry of Home Affairs in Northern Ireland which restrict more narrowly than heretofore the qualifications for office as a dispensary medical officer or district medical officer of health. Until the issue of these regulations the usual medical qualifications and evidence of instruction in vaccination were the only qualifications required for these offices in Northern Ireland. The appointments were made by local boards of guardians but were subject to the approval of the Minister of Home Affairs. On Nov. 26th 1937 the Minister made new regulations which added the new condition that the officer must have been resident in the United Kingdom of Great Britain and Ireland for a period of five years prior to appointment. It had happened that on Nov. 14th 1937—twelve days before the making of the regulations—the Newry guardians had elected Dr. John Francis McGeough of Swan Park Monaghan to be medical officer of the Mullaghglass dispensary district in their union and had forwarded his name to the Ministry for approval. After some delay the Ministry refused approval on the ground that it would be contrary to the regulations of Nov. 26th. Dr. McGeough not having resided in the United Kingdom for the requisite period and directed the Newry guardians to proceed to make a fresh appointment. Dr. McGeough obtained a conditional order of mandamus directed to the Secretary to the Ministry calling on the Ministry to sanction his appointment, on the ground that the regulations having been made after his election they could not apply to him. Last week the application was made to make this conditional order absolute and it was refused by the two judges Mr. Justice Brown and Mr. Justice Megaw. The judges do not appear to have decided whether Dr. McGeough was subject to the regulations or not but holding that there was an absolute discretion as to approval resting in the Minister the issue of an order would be useless.

Apart from the consideration of the particular case of Dr. McGeough the making of the regulations has caused uneasiness among the profession in the Irish Free State. Hitherto there has been free trade between the United Kingdom and the Irish Free State as far as the medical profession is concerned. The qualifications of the universities and the licensing bodies in the Irish Free State carry admission to the Medical Register equally with the qualification granted in Northern Ireland. Conversely all those whose names are on the Medical Register can claim admission to the Medical Register of the Irish Free State. Medical men resident in or educated in Northern Ireland or Great Britain are free to be elected to any medical position in the Irish Free State and many of them hold high positions in the public medical services there. Until the framing of these regulations medical men from the Irish Free State were eligible to hold any public appointment in Northern Ireland and in common with their fellow from the overseas Dominion they are eligible for admission to His Majesty's Forces of the United Kingdom and in fact have gained distinction and held high offices in their medical services as well as in the civil service and in the service of local authorities. It would be an anomaly that Northern

Ireland should offer the only exception to this general freedom of employment. As regards many of the younger graduates who are natives of Northern Ireland the regulations may cause special hardship. Many young men from the north come to the Dublin schools of medicine for their education. On their return to their homes they will find themselves debarred from competing for public appointments, not having been resident in the United Kingdom for the requisite period of five years. It is understood that the regulations are viewed with repugnance by the medical profession in the north, and the hope is expressed in medical circles in the south that the Ministry may think fit to cancel them.

PARIS

(FROM OUR OWN CORRESPONDENT)

TUBERCULIN TESTS OF NURSES AND CHILDREN

THE Academy of Medicine has been hearing a lot about tuberculin testing. On April 6th a team of workers from the Beaujon Hospital in Paris presented a report on Pirquet and Mantoux tuberculin-testing of 100 nurses between the ages of nineteen and thirty. It was found that 23 of them were negative reactors even when large doses of tuberculin were given by intracutaneous injection. When they were classified according as they had or had not lived for many years in Paris, no difference was demonstrable in the proportion of negative reactors, but when they were classified according to age, it was found that whereas 28 per cent of those under twenty three were tuberculin negative, the corresponding figure for those above that age was only 15 per cent. This confirms old teaching that the proportion of negative reactors dwindles with age, but it seems remarkable that as many as 23 per cent of these nurses should have remained uninfected despite the countless opportunities provided by a big general hospital.

On April 13th the Academy received a report on the tuberculin testing of 1048 children under the age of fourteen—among them 119 who in infancy had been given BCG by mouth. Dr Armand Delille, who was responsible for this study, undertook it because he wanted to verify the now common assumption among his colleagues that BCG makes the Pirquet reaction positive, and that it is therefore useless to employ this test in children who have been given BCG. This assumption seems unjustified, for the proportion of tuberculin reactors was almost the same among the BCG children as among the controls. Be it noted, however, that the observation applies only to BCG given by the mouth at birth in three doses, and not to BCG given by subcutaneous injection. This communication from Armand Delille and his collaborators drew some interesting remarks from Dr Guérin, who dealt at some length with the allergic responses of the tissues to BCG given by the mouth. He was inclined to think that more frequent and larger doses of BCG given by the mouth may be advisable.

PROFESSORSHIPS IN MEDICINE

What may be described as a preliminary and quite tentative taste of immortality is the recent creation of a new class of professor—*professeur de classe exceptionnelle*. As from Oct 1st, 1937, eight professors of the first class have been promoted to this rank, which allows them to remain in office till they reach the age of seventy. The distinction has been conferred on two provincial professors, Berard of Lyons and

Boun of Strasbourg. The six Parisians are Bezançon, Carnot, Claude, Gosset, Ombrédanne, and Tiffeneau.

Another event of importance in the academic world is the creation of a new chair of medicine. Its occupant is to be professor of "*assistance médico sociale*" or "*médecine sociale*." This being interpreted means sickness insurance and all the new machinery which has grown up around it. The new professor will be expected to teach fifth year medical students the elements of *social medicine*. Such teaching should save the young medical practitioner of the future much racking of brain and insurance officials much revision of ill drafted certificates. The new professor, who will enter on his duties next October, will rank as a third class professor in the Paris faculty of medicine, and his emoluments will be 60,742 francs.

LEPROSY IN PARIS

At the end of 1934 the leprosy service of the Saint-Louis Hospital in Paris was confided to Dr C Flandin who, in association with Dr J Ragu, presented a disquieting report on the subject at a meeting of the Academy of Medicine on March 16th. When Dr Flandin took charge of this service there were only 4 lepers in it, now it houses 26, and 69 others are under his observation either at the hospital or elsewhere. There are several reasons for this remarkable rise in so short a period from 4 to 95 cases of leprosy. In the first place, the greatest tact has been shown in dealing with the lepers, who are most sensitive to being treated as exhibits for medical students. In the second place, these patients have been assured that professional secrecy will be preserved with regard to them and that no step will be taken to intern them against their wills. A third inducement to lepers to come forward and submit to diagnosis is the success here believed to result from intravenous injections of a new preparation of chaulmoogra oil and cholesterol. Among the 95 patients were 41 whites who had passed some time in the colonies, 17 whites who had been born in the colonies, and 6 whites who had never left France. The remaining 31 patients were coloured or half-breeds. Four of the Europeans who had contracted the disease in the colonies had stayed there only 4 to 10 months, their incubation period ranged from 8 months to 25 years. The enormous differences in the length of the incubation period may in part be explained by a reference to the mode of infection, the comparatively short incubation period of 6 to 8 months is to be observed in patients contracting the disease by sexual intercourse with a leper, whereas comparatively long incubation periods are the result of mere residence in a leprosy milieu. This was the case with 2 of the 6 cases of leprosy in persons who had never left France. In the remaining 4 cases the infection was conjugal. Now that it is definitely proven that leprosy can be contracted in France there may be a renewed clamour for compulsory notification and isolation, but Dr Flandin is definitely opposed to such a course, being convinced that it will defeat its own object by driving leprosy underground. The measures he favours include facilities for diagnosis and treatment at a hospital, such as the Saint Louis, which should be in touch with all the bodies working on behalf of lepers in France. In the course of the discussion following this communication to the Academy, Dr Marchoux agreed with Dr Flandin as to the undesirability of compulsory notification, and he considered the best solution of the problem to be the leprosy dispensary and supervision of the lepers by visiting nurses. His

suggestion that a commission should be appointed by the Academy to deal with this problem was accepted and Dr Flandin and Dr Ragu a report was referred to a commission on which five leading members of the Academy will sit

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

PUBLIC HEALTH IN NORTH AMERICA

ON April 3rd health officers from the several States and from the Canadian provinces began to arrive in Washington. They stayed long enough to see the famous Japanese cherry blossoms give their brief annual display around the tidal basin at the end of the following week.

The rapid expansion of public health programmes under the Security Act has thrown a great strain upon the postgraduate teaching facilities of the U.S. medical schools. Professors of public health administration and other members of the faculties were present from Harvard, Yale, Johns Hopkins, Columbia, Vanderbilt, Michigan, Minnesota, Duke, the Massachusetts Institute of Technology and the University of California. The University of Pennsylvania was represented by Miss Katharine Tucker of the School of Public Health Nursing. Short courses of training for health officers lasting for three to four months have been given as an emergency measure. Their value is variously estimated. Some educators believe that older men have scarcely time in three months to rediscover themselves in a school environment. Others felt that the courses do have a limited usefulness. All agreed that they were designed only for the emergency, but it was obvious that in some States the emergency is not yet over.

The suggestion that the long course lasting for one academic year and leading to the degree of C.P.H. might prove an expensive investment by the Government, since many of the graduates might return to private practice led to a rapid compilation by Dr Allen Freeman of the present status of C.P.H. graduates from his school. He shortly announced that of the 404 men who have taken the C.P.H. degree from Johns Hopkins only 26 have gone back into private practice. 17 are practising in the U.S. and 9 in foreign countries. Dr Haven Emerson said that Columbia University is getting an increasing number of private practitioners who study public health at their own expense but without any idea of ever leaving the private practice of medicine.

There was general agreement that despite the larger increase in the number of physicians studying public health their quality as students compared well with that of previous classes. Very general agreement was expressed also with the view that in addition to the year's training in a school of public health the would-be health officer should serve an apprenticeship in the field under the direction of an experienced administrator.

In the training of public health nurses emphasis was placed on the importance of a good basic training in nursing as a prerequisite to admission to post-graduate work. The general work of a public health nurse should also be completed before courses are offered in specialised nursing as for example in tuberculosis or syphilis. If short courses are to be given they should not be condensations of the regular course but units which can eventually be added together into a long course.

On the morning of April 5th we enjoyed two addresses by visitors from Great Britain. Dr Thomas Anwyl Davies, director of the Whitechapel V.D. Clinic was introduced by Surgeon General Parran and described to us the encouraging results of the work in London with which you must be familiar. He also spoke of his experiments with an antitoxin for gonorrhoea that has so far received no experimental confirmation in America but which is now under investigation at Columbia University. Dr Abraham J. King was introduced by Dr R. L. Wodchouse, deputy minister of health of Canada. He spoke on the public health control of gonorrhoea in Great Britain.

Dr Rufus Cole, director of the hospital of the Rockefeller Institute, reported the latest progress in the development of pneumonia serum. It is found that antibodies developed in one species of animal differ from those developed in another species, one difference noted being in regard to the size of the molecule. The molecule of the antibody developed in a rabbit is smaller than that of the antibody developed in the horse and as might be expected, the rabbit antibodies appear to diffuse more rapidly. Rabbit serum is also produced much more cheaply since rabbits are rapidly immunised and respond quite consistently. The use of rabbit serum so far has been limited but is promising.

Dr I. W. Jackson, deputy minister of health of Manitoba, gave a thorough epidemiological description of an outbreak of poliomyelitis in his province. The provision of free diagnostic service had had a most salutary effect in bringing cases promptly under care. After this service was made available treatment was commenced in every case within 24 hours of the onset of symptoms and no more deaths or cases of residual paralysis were observed. An unusual feature of the epidemic was the high rate of secondary cases in the quarantined families.

Dr Estella Ford Warner opened a discussion on the place of health education in schools and among adults. The 48 States all provide some programme of health education but there is no uniformity of practice. Insufficient use is made of the facilities of existing educational agencies. Dr Parran announced the inauguration of a consulting service of health education in Washington. A service to give advice on the progress of the science of nutrition will also be provided. Nutritionists—or specialists in this science—are employed already in several States. The need for a special division of a State health department in this field is not yet generally accepted.

THE CHILDREN'S BUREAU

I wrote a year ago of the expanding field of public health activity. Reports given by the Children's Bureau to the State health officers on April 8th marked the extent to which this expansion has progressed during the year. \$80,000 of federal funds and \$17,000 of State funds have been paid out to private practitioners for conducting clinics for well babies or for expectant mothers or for crippled children. Dental clinics have also been subsidised and 54 dentists are employed on the staffs of State health departments. Consultation services in obstetrics have been very cordially welcomed by the practising profession and in several States antitoxins conducted by members of university faculties in obstetrics or pediatrics have been well attended. Important recommendations were adopted at this session looking to analysis of the causes of maternal deaths by the State health department in co-operation

with the State medical societies with a view to raising the standards of obstetric practice, and also to the public employment of "qualified" nurses for maternity service. The American method of attacking the problem of providing medical care for the indigent begins to shape itself. Care will come in categories. The tuberculous, the syphilitic, the insane, are already widely recognised as social responsibilities. Cancer is being added. Heart disease is recognised in some States. New York and Massachusetts have broached the case of pneumonia. The work of the Children's Bureau extends the conception of social responsibility to obstetrics and paediatrics. The full time medical employees of the State and Federal Government will not increase greatly in numbers, but will as rapidly as possible be raised to higher standards of professional qualification, and it is to be hoped will be removed further from partisan political influence and given greater security of tenure. In the growth of this programme the help of the private practitioner will be sought and will be rewarded. Every effort will be made to see that he, too, has opportunities to keep abreast of the times and to improve his professional technique. If health insurance has any place in this American scheme it will only be as one far from dominating feature of the whole plan. Probably it will be tried out first on a small and experimental scale, to be judged by its ability to conform to the general outline of the larger plan of what has been described as "limited State medicine with private practice."

VIENNA

(FROM OUR OWN CORRESPONDENT)

WELFARE OF THOSE WITH HEART DISEASE

A COMMITTEE consisting of the foremost pathologists, medical men, and philanthropists, and also including the leaders of the Government and the Church, has recently founded a Society for the Welfare of Heart Patients, which at first will be active in Vienna itself, but will soon be able to extend its scope to the whole republic. In the pamphlet issued by this society, competent authors point out that the statistical data prove the alarming increase of cardiovascular trouble amongst the population. Whereas formerly tuberculosis and neoplasms were the principal causes of death heart disease now heads the mortality statistics. A few figures will serve as illustration. In 1932 there died in Austria 28 62 persons from tuberculosis against 86 26 who succumbed to cardiovascular diseases (per 10,000 living). The percentual picture is the following. In 1905 10.4 per cent of the deaths were due to tuberculosis and as many to heart disease, in 1932 only 7.5 per cent died from tuberculosis, but 22.7 per cent from heart disease. Thus in 27 years the mortality in the one had decreased by 30 per cent but in the other it had doubled. Furthermore, investigation amongst apparently healthy labourers showed that 15 per cent of all factory hands aged 20-30 had more or less definite symptoms of circulatory disturbance. In the age group 50-60 this figure went up to 65 per cent, in other words, two thirds of these persons doing physical work during their adult life have suffered definite damage to their cardiovascular system. A follow up of patients observed in the Vienna Herzstation within the last two years has proved that 17.5 per cent were incapacitated in their occupation or profession.

This was due partly to the disease itself, partly to social, economic, and dwelling conditions, such as lack of means to buy expensive medicines, and living in high storied houses without a lift, with overcrowded rooms and want of rest and quiet. The new society has therefore decided to make the following its aims: the erection of special homes for heart disease, with sanatoriums providing appropriate rest and exercise, the training of special nurses, and instruction of heart specialists, the collection of funds for future improvements, including the setting up of welfare centres in the country, of ambulatory classes for instruction of affected persons, and of a special museum. This society will of course coöperate with the existing clinics and similar welfare centres, to prevent double track work.

AN INTERNATIONAL CONGRESS

Under a patronage of the Austrian Federal Government, and with Prof d'Arsonval and Marchese Marconi as honorary chairmen, the first International Congress on Short Waves will be held in Vienna on July 12th-17th. Its transactions will deal with the relationship of short waves to physics, biology, and medicine. In the first section, therefore, the congress will discuss their properties, generation, conduction, detection, and measurement, their action on chemical systems, and finally the different methods of application and the uses of short waves. The biological section will bring papers on the action of short waves on plants and animals, on tissue cultures, on enzymes and ferments, and on their thermic effects. The third section will discuss the indications and contra indications of short wave therapy in the various branches of medicine and surgery. All the latest achievements and the technical methods and apparatus will be described. There will also be social functions, and interesting excursions through the Alps will be provided for the members. The secretary of the congress, Dr Liebesny, may be addressed at his office in the Vienna Allgemeines Krankenhaus.

A DOUBLE CHANGE OF SEX CHARACTERS

At a recent meeting of the "Gesellschaft der Aerzte," Prof Nowak and Dr Wallis demonstrated an unusual and interesting condition in an unmarried woman aged 32. Two years ago her hitherto regular menstruation ceased and considerable changes in her appearance took place. The growth and distribution of her hair became masculine in type, the face became coarse, the voice deep, the muscles firmer, and the clitoris grew in size. Besides this an extensive acne appeared on the body, the typical fat deposits disappeared, and the mammae diminished in size. The effect was a very noticeable masculinisation of the woman. More detailed examinations showed an increase of erythrocytes (8,600,000), a rise in blood pressure to 145 mm Hg and in blood sugar to 150 mg per 100 ccm. Folliculin could not be detected either in the urine or in the blood, and prolactin was also absent in the urine, but on the other hand no masculine sex hormone was discovered. The patient was found to be suffering from a tumour of the right ovary, which was removed. Four weeks after the operation menses began again and have since remained regular. All the masculine attributes soon receded, the voice and the habitus becoming once again female in type. This included also a drop in the erythrocytes, in the blood pressure and blood sugar. Folliculin could now be found in the urine in normal quantity, but prolactin remained absent. The histological examination of the tumour proved it to be built up of the so called interstitial cells but its

histogenesis is not yet clear. This case of sex alteration with increase of blood pressure of the number of red blood-cells, and with hyperglycemia is most likely to be a case of "interrenalism." Probably the tumour that was removed from the ovary originated from isolated cortical adrenal tissue; such tumours are not uncommon and their effect on the sexual status is well known. In this case however histologists could not agree about the

exact nature of the tumour. Since the adrenal cortex and the tissue of sexual glands originate from the same matrix it is possible that in certain instances a tumour can form from this fundamental substance, which differs from the adrenal gland and the sexual gland but contains functional qualities common to them both. A remarkable feature in this patient was the rapidity with which the changes took place in both directions.

GRAINS AND SCRUPLES

Under this heading appear week by week the unfettered thoughts of doctors in various occupations. Each contributor is responsible for the section for a month; his name can be seen later in the half yearly index.

FROM A MEDICAL ECONOMIST

II

KINGS are anointed with oil for the same reason as sacrifices used to be anointed—to ensure burning. The symbolism in these days, is obscure but in earlier days all men understood and approved.

In earlier days a king was his people's most valuable possession. This was no embellishment of courtiers; every man knew it. Every man saw in the King's grace his own dearest interest and was eager therefore, that the utmost honour should be accorded to Majesty. It may sound an overstatement but it is a sober fact that only those peoples could be strong and secure who possessed good kings.

The point is worth making at a moment when it seems to be generally accepted that the world is faced with a choice between democracy and dictatorship. What is democracy? What is dictatorship? And how does it come about that these two exhaust all the political possibilities? The answer which is commonly given is that in fact, there is no third choice because a constitutional monarchy is a form of democracy whereas an autocratic monarchy is a form of dictatorship.

* * *

This it is worth recalling was not Disraeli's view. That great statesman proclaimed that monarchy was not only the most recent historically of all forms of government but was also so exalted a form that only men of real understanding could measure its worth. He was not speaking of constitutional monarchy—he was certainly not speaking of the kind of monarchy which for example the Tarquins bestowed upon Rome. What Disraeli had in mind was a king whose power proceeded in the first instance from himself alone without reference to armies of parties or factions—without reference even to popular election. Ibsen had the same idea. He made one of the characters in one of his historical plays declare of a Norse king that he possessed the king thought.

It is a matter of knowledge that dictators are always party leaders. They command a class—whether the army or the nobility or the merchants or the proletariat or persons of some special political complexion. The dictator has come to power as a rule because his party has come to power. He acts for and by his party and professes to see in its philosophy the only means of national salvation. If he is a soldier the moral virtues of soldiers are exalted and the structure of society is remade on military lines. If on the contrary he is the leader of Jacobins or Bolsheviks the opponents of these factions will be attacked and destroyed.

Parties however parties of the Right as well as parties of the Left have one feature in common—all possess secret funds. None except a small circle knows who are the subscribers to the party funds and none therefore can really say whether or not the policy of the party is sincere. The chief subscriber to a party of the extreme Left, for example might be a millionaire of the extreme Right and that fact might be known only to a handful of party managers—it is conceivable even that not a single manager might know the real source of the support. But what would happen in such a case would be that if the party began to act in a way contrary to its backer's wishes, its money would evaporate and all its officials would be ruined. In such circumstances a break up of the party could scarcely be avoided.

It is when dictatorship is viewed steadily from this point of view that its likeness to rather than its difference from some forms of democracy becomes apparent. Democracy consists usually of a group of parties each possessed of financial backers. Dictatorship arrives often enough when one of these parties savages all the others by reason of its more substantial backing or because the backers of the opposing parties have withdrawn their support.

It will be objected that parties compete for popular support and cannot be returned to power unless they secure it. But popular support in these days of mass electorates means propaganda on the great scale and propaganda on the great scale is exceedingly costly. Unless a party possesses backers it cannot hope to win. It does not follow of course that all backers are interested persons. The backers of a party may be as sincerely convinced of the value of its aims as the humblest members. Nor need they necessarily be rich men. The point is that there must be backers of one kind or another if the party is to come to power and this applies to military as well as to civil parties.

The dictator therefore like the democratic government is elected on what Americans call the party ticket and will be compelled to consult the interests of the party. This will be easy for him so long as party interests and national interest are the same or rather so long as he remains convinced that they are the same. But it is always on the card that an issue may arise whereby the party and the nation are set in opposition. In that hour the dictator will have to choose between the body which made him dictator and the people upon whom his leadership has been imposed whether by force or by persuasion.

It is a choice which comes sooner or later to almost every dictator. It came to Cromwell weary of the tyranny of Parliament in arms who wanted to make himself King of England and would have done so had not the Iron sides prevented him. It came to

Robespierre when, sickening of the Terror, he tried to quell the Jacobins. The Jacobins destroyed him and historians ever since have pointed the moral that revolutions tend to eat their own children—an erroneous reading. It came later to Napoleon, when he felt himself being forced back upon the soldiers of the Revolution. He succeeded in bringing all the parties, including the soldiers of the Revolution, into subjection. One modern dictator is now experiencing the same choice and has turned against the old guard of the Communist party—successfully as it seems. Another a few years ago attacked and broke the old guard of his own party. The old guard of the Democratic Party in the United States continues to assert that the President has undermined the party's position and strength.

That these are events of great significance few will dispute. What do they mean? The dictator who refuses to obey his party and its backers can look for support in one direction only—namely, the nation. Only if he can secure the nation's support can he hope to survive.

* * *

It is matter of history that the support of nations is given to very few men and that these men bear, always, a close likeness to one another. That likeness does not reside in intellectual power, though intellect is usually highly developed. Rather it is an emotional quality of rare and potent nature by which a man is able to make himself the beloved and trusted of millions of his fellows. I do not doubt that Ibsen was right when he declared that only he who possesses the King thought can exercise such power. In other words the power belongs to the leader and proceeds out from him to the people. Disraeli identified this power with love and looked upon Kingship, in consequence, as a marriage of one man to a nation.

The King was the people's bridegroom. Like a bridegroom he was ready—and the people knew it—to sacrifice himself for them. His people called him lover and father and made his consecration manifest by anointing him with the sacrificial oil. "The grace of God in a King," said Pope Gregory the Great, "is the power to protect the sheep from the wolves. If a King does not possess that power he is without grace and is no King." Napoleon said the same thing in different words. "Without a King there is no people, there are only parties. The party with the most money wins when it has to reward its financial backers."

The King then is a leader who has wooed and won his people by virtue of his King thought. This is no party dictator nor popularly elected party chief, but a being in ecstasy who, by mystical process of love, has ceased to care for self or safety and become father and comforter. Every notable man in the land will now be forced to serve the people, for King and people united are irresistible. For this reason symbolism set crowns also, the garlands of sacrifice, on noblemen's brows. For this reason noblemen who attempted to oppose the King, to seize their lands in absolute title, and to make of their folk serfs and chattels, were attacked by Majesty. For it was, as it is, the first business of a king to bend all the notable men, the barons, to the people's service.

There is the world of difference between Kingship in this real sense and representation. It is obvious that power cannot, in fact, originate with the people since, without leadership, the people is helpless and falls, always, into the hands of wolves. But it is equally obvious that without the people's love the king is helpless. King and people therefore are one, like father and children. It is the King who creates the people since it is his King thought, his word, which is made flesh in them.

PANEL AND CONTRACT PRACTICE

The Practitioners' Fund

THE negotiations for an increased capitation fee as well as the controversy regarding the payment in respect of the 14-16 year adolescents has focused attention upon the capitation fee. There are few practitioners, if any, who receive from their insurance committee exactly nine shillings multiplied by the number of persons on their list in any year and, doubtless, many have wondered exactly how their remuneration is calculated. Many committees send out a detailed statement with each cheque, but this, after all, merely explains the distribution of the areal practitioners' fund and not how the fund itself is calculated. The chairman of the London medical benefit subcommittee has just answered a question on this subject at a meeting of the insurance committee, and his reply provides a concise statement of the method adopted in calculating the practitioners fund.

The method by which the amount of the areal practitioners' fund is arrived at is broadly speaking as follows. Out of the sums available for medical benefit the central practitioners' fund is set up at the beginning of each year. It is calculated on an estimate made by the government actuary of the number of insured population entitled to medical benefit multiplied by 9s. The estimate is arrived at mainly on the basis of sales of health insurance stamps. The final amount of the central practitioners' fund is not known until after the end of the year, but each year the committee are notified during February of the

amounts which may be distributed quarterly within the final determination of the fund. The balance usually becomes known towards the end of February in the succeeding year, and a final settlement is effected as soon as the necessary calculations can be completed.

The central practitioners' fund is distributed among insurance committee areas by the Minister of Health after considering the report of the medical distribution committee which consists of representatives of insurance practitioners, of insurance committees, of the government actuary, and of the Ministry. This committee have before them particulars as to the insured population in each area (this being based upon what is known as the count of the index register). It is their duty to make a fair and just apportionment of the total fund between the several areas. They take into consideration such factors as the incidence of temporary residents (this in London invariably means a deduction but in some areas it causes quite an appreciable addition). Deductions are also made in respect of insured persons obtaining medical benefit through approved institutions and making their own arrangements, and also for members of the mercantile marine. A final net proportion is then ascertained and the central practitioners' fund is distributed on this basis. The areal practitioners' fund has to be distributed among practitioners on the basis of their respective figures of credit, but even here there are various adjustments to be made—e.g., in respect of the administrative

expenditure of the local medical and panel committee and of payments to practitioners for the cost of the provision of anaesthetists and emergency treatment.

It will be clear that although at the source the central practitioners fund has been based on an estimate of the insured population multiplied by 9s the areal practitioners fund as calculated does not necessarily represent the local insured population multiplied by 9s it may be either above or below this figure. In the administrative county of London up to 1933 the unit value was actually less than the nominal 9s value but the clearance of the medical register which took effect as from Jan 1st 1934

reduced the number of units of credit upon which practitioners remuneration was based without affecting the calculation of the areal practitioners fund. The result was that whereas for 1933 the value of a unit of credit in London was 7s 11-40524d in 1934 the equivalent value was 8s 7-4032d. This was at a time when economy deductions were being made from the remuneration of practitioners. For the year 1935 the figure rose to 9s 1-17192d but this increase was accounted for mainly by the restoration of the economy deduction of 5 per cent which operated only for the first six months of that year. For the year 1936 the total payment will amount to 9s 2-5254d.

CORRESPONDENCE

AMBULANCES AND STRETCHERS

To the Editor of THE LANCET

SIR—I am glad that Dr Lockhart noticed my letter because it was his letter published in your column two years ago which stimulated my interest in this subject.

I quite agree with him that the universal adoption of a standard stretcher with telescopic or folding handles would simplify our problem but I do not think that the fighting services of any nation would agree. They would not consider such stretchers capable of standing up to the rough usage of war. I realise the great advantages of short stretchers when it comes to carrying them in lifts railway-carriages air ambulances and boats (we in the Navy have a short stretcher) but I cannot envisage the abolition of long stretchers and I still think that ambulances capable of carrying long or short stretchers should be adopted where practicable.

Standardisation of gauge as Dr Lockhart points out is essential.

I am Sir yours faithfully

R. A. W. FORD

R.M.S. Hood May 3rd Surgeon-Commander Royal Navy

INSULIN AND GASTRIC SECRETION

To the Editor of THE LANCET

SIR,—At a meeting at the Royal Society of Medicine on March 9th Prof E. C. Dodds and Dr R. J. Noble reported observations on the action of insulin on the gastric secretion of cats. Having several years experience with insulin as meal for fractional tests I should like to bring out the following points.

1. Insulin stimulates gastric secretion sufficiently to enable one to discriminate between pseudo-acidity and true acidity just as often as one can with histamine.

2. The stimulus to the stomach is the hypoglycaemia, acting through the vagus (as stated for example by Heller¹ and by Dodds and Noble² but questioned by Meyer³). The test is therefore not suitable for diabetic patients.

3. Whereas histamine sometimes produces undesirable side-effects which may be difficult to overcome the insulin test using the doses stated below rarely causes symptoms requiring treatment. In the few cases which developed hypoglycaemic symptoms (1) at were at all serious I have nearly always been able to control them by oral administration of sugar and it has very seldom been necessary to give intravenous glucose injections.

¹ Dodds E. C. and Noble R. J. (1935) *Proc. R. Soc. Med.* 30, 815, see also *Lancet* March 20th, p. 692.

² Heller R. (1931) *Med. Klinik* 27, 1451. (1931) *ibid.* 27, 1451.

³ Meyer I. F. (1930) *Klin. Wochenschr.* 8, 1578.

4. It is an advantage that the secretion obtained is not mixed with any fluid given as test stimulus.

5. The optimal amount of insulin was found to be 12-15 units (Heller¹). The secretion starts about 20-40 minutes after intravenous (or about one hour after subcutaneous) injection. In patients with normal gastric secretion 55-75 are the highest values for free acidity and 75-85 the highest values for total acidity.

6. The stimulating action of insulin on the gastric secretion shows that the administration of insulin is contra-indicated in fattening cures in patients with hyperacidity.

Each of these points has already been made by Meyer and/or Heller.

May I take this opportunity to remind your readers that in distinguishing hyper from hypo glycaemic coma a positive Babinski sign proves the coma to be hypoglycaemic. Whereas the differential diagnostic value of flaccidity in hyper and of spasticity in hypo glycaemic coma is mentioned in many text books and papers a reference to Babinski's sign is very rarely to be found.

I am Sir yours faithfully

HERBERT LEVY

PRURITUS ANI

To the Editor of THE LANCET

SIR,—Surgical news about pruritus ani is as attractive as it is varied and the announcement in your issue of April 17th of the pruritic stage of pruritus ani is quite delightful. I suspect that Mr. Riddoch wrote his article with his tongue in his cheek but he has allowed fiction so heavily to outweigh fact that some little protest must be entered. The codema of the skin which might seem to give the stamp of reality to his theory is in fact the finding common to all itching and rubbed skins though it is more readily provoked in the skin of the genitalia and perineum and of the areola. It is not true that itching is apt to occur more frequently about the various body orifices than elsewhere; it is not even true of the vulva and anus; it is less true of the ears nose mouth and urethra. Does Mr. Riddoch seriously suggest that X-ray therapy is curative because of its destructive effect on the vessels? This is alarming.

With the courage characteristic of the surgeon he dismisses the psychological side of the problem but Carlyle was wiser than Mr. Riddoch imagines. There is no doubt of the pleasure associated with itching especially anal itching, as the majority of subject with pruritus ani will confess. Indeed it is the

indulgence in this pleasure which too often creates the habit which is so difficult to break.

I am, Sir, yours faithfully,

Leeds, May 3rd

JOHN T INGRAM

To the Editor of THE LANCET

SIR,—In your last issue Dr Browne Carthew mentions that I did not refer to radium in the treatment of pruritus ani. I could not possibly mention all the various forms of treatment that have been tried in this condition and I have come across only one reference to the use of radium (O'Donovan, W J (1936) *Practitioner*, 136, 148). However the fact that O'Donovan claims good results from its use, coupled with Dr Browne Carthew's remarks, lends further support to my thesis. Well over 90 per cent of cases can be cleared up by the simpler method of sclerosing injections in the internal hæmorrhoidal area if these are efficiently carried out, and the remainder must be dealt with to suit the individual case, as for example when one has to stretch a fibrosed anal canal or remove tags or fibrosed internal hæmorrhoids, &c., as well as destroy the subcutaneous veins by undercutting of the skin, sclerosing injections, or possibly radium.

I am, Sir, yours faithfully,

Birmingham May 4th

J W RIDDOCH

PERNICIOUS ANÆMIA IN AN INFANT

To the Editor of THE LANCET

SIR,—I was interested to read in your issue of May 1st an account of a case of macrocytic anæmia which occurred in infancy in association with achlorhydria and high icterus index and which responded rapidly to treatment with liver. I venture to doubt however whether the authors are justified in labelling the case "pernicious anæmia," and I would suggest that it is one of subacute hæmolytic anæmia.

During the past few years macrocytosis has been recognised and described in an increasingly large number of disorders of the blood. In a series of hæmolytic anæmias in infancy and childhood admitted to the wards of the Birmingham Children's Hospital and to be published shortly, I have observed several examples of macrocytic anæmia some of which have failed to respond to transfusions of blood or the administration of iron. They have, however, reacted well to treatment with liver, as did the case described by Prof Langmead and Dr Doniach. In each case treatment with liver was discontinued after complete hæmatological recovery, but the anæmia did not relapse. This fact differentiates the pernicious like picture of subacute and chronic hæmolytic anæmia from true Addisonian pernicious anæmia, for in the latter condition the anæmia will always recur unless sufficiently large doses of a potent liver preparation are given regularly. Time and further blood examinations alone will tell whether or not the case of Prof Langmead and Dr Doniach can be accepted as one of true pernicious anæmia of infancy.

PRISONERS AND CAPTIVES

To the Editor of THE LANCET

SIR,—I regret having to inform Dr Vasefield that I weighed my Grains and Scruples very carefully indeed. The result was disconcerting. However, I can relieve his distress in at any rate one respect, my criticism was, and is, directed at the system,

not directly at any of my medical colleagues. The system does seem to me to be needlessly cruel, in that it shuts away indefinitely young people who are a danger neither to themselves nor to anybody else. And—thus I feel acutely—few, not being official people, ever see the inside of the institutions referred to. Official people, however humanitarian, tend to become more and more official, specialists, however kindly, do come to look through ever narrowing spectacles.

I know, from bitter experience, that it is infinitely more easy to get a young person into an institution for the mentally defective than it is to get him out. I am convinced that there are, at this minute, young people in such institutions who would be better in every way if they were outside. I interviewed one of them recently in an institution.

There are some of us who feel, strongly, that all is not well. That is why I wrote as I did, and why I hope to write further when, and where, the opportunity arises.

I am, Sir, yours faithfully,

April 30th

TADDYGADDY

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 24TH, 1937

Notifications—The following cases of infectious disease were notified during the week. Small pox, 0, scarlet fever, 1647, diphtheria, 1027, enteric fever, 32, pneumonia (primary or influenzal), 804, puerperal fever, 41, puerperal pyrexia, 114, cerebrospinal fever, 23, acute poliomyelitis, 3, acute poli-encephalitis, 2, encephalitis lethargica, 4, dysentery, 33, ophthalmia neonatorum, 111. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 30th was 3140 which included Scarlet fever, 846, diphtheria 904, measles, 45, whooping-cough, 608, puerperal fever 13 mothers (plus 10 babies), encephalitis lethargica 284, poliomyelitis 1. At St Margaret's Hospital there were 21 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths—In 123 great towns, including London, there was no death from small-pox or from enteric fever, 12 (0) from measles, 5 (2) from scarlet fever, 22 (7) from whooping-cough, 30 (3) from diphtheria, 30 (12) from diarrhoea and enteritis under two years, and 47 (5) from influenza. The figures in parentheses are those for London itself.

Four deaths from measles were reported from Kingston upon Hull, 5 deaths from influenza at Birmingham. Liverpool had 4 deaths from diphtheria and 3 from Manchester. There were 4 deaths from diarrhoea and enteritis under two years at Birmingham and 3 at Newcastle-upon Tyne.

The number of stillbirths notified during the week was 201 (corresponding to a rate of 41 per 1000 total births), including 53 in London.

MEDICAL CONFERENCE IN SWITZERLAND—A third international medical week has been arranged by the *Schweizerische Medizinische Hochschrift* and will be held at Interlaken from August 20th to Sept 4th. The speakers will include Prof Hugh Cairns (results of treatment of intracranial tumours), Prof Clovis Vincent, Paris (treatment of subacute and chronic abscesses of the brain), Prof O Loewi, Graz (the chemical transmission of nerve stimulus), Prof K I Anselmino, Wuppertal Elberfeld (relation of the pituitary to carbohydrate metabolism and to diabetes), Prof L Lichtwitz, New York (disturbances in the regulation of carbohydrate metabolism), and Prof H Spemann, Freiburg in Breisgau. Further information may be had from the secretariat, Klosterberg 27, Basel.

OBITUARY

SIR PATRICK HEHIR K.C.I.E. FRCP,
F.R.C.S. F.R.S. Edin
MAJOR-GENERAL, I.M.S.

Sir Patrick Hehir who died on Saturday last May 1st at Hove, was a distinguished member of the Indian Medical Service holding at different times high and responsible office and being deeply interested in both the social and scientific side of tropical medicine.

Patrick Hehir was the son of Robert Martin Hehir of Ennis Co. Clare. He received his medical education in Edinburgh and at Guy's Hospital qualified as M.R.C.S. Eng. L.S.A. in 1885 and took the diploma of F.R.C.S. Edin. in the same year. He graduated later as M.D. Brux.

SIR PATRICK HEHIR

(Photograph by Elliott & Fry)

He joined the Indian Medical Service in 1886 and immediately saw service in Burma and Tirah. He was engaged in the latter campaign during 1897 and 1898 and received a medal with clasps. He was next serving on the Mohmand expedition but in 1898 returned to Burma as Assistant Director of Medical Services. Shortly afterwards he was transferred to Poona holding the same position in the Bombay presidency while at the outbreak of the war he was at headquarters Simla, as Deputy Director of Medical Services. He was therefore a very experienced officer when his eventful career during the war commenced. He was engaged in the campaign in Mesopotamia and was several times mentioned in dispatches for his excellent work. At the surrender of Kut he was taken prisoner by the Turks and until his release did valuable work in caring for the sick and wounded especially the Indian contingent. Released by the Turks he took up his appointment at headquarters in India as D.D.M.S. and in recognition of his fine work received the orders of C.B. and C.M.G. In the second Waziristan campaign he was again to the front as D.D.M.S. and in 1919 further hostilities in Afghanistan gave him an opportunity of earning credit for he was mentioned in dispatches and promoted K.C.I.E. having received the C.I.L. the previous year.

Throughout his long service in India Sir Patrick Hehir was engaged in efforts scientific and social to prevent and control malaria in India. He made many personal researches into the life history of mosquitoes and in 1910 produced his work *Trophylaxis of Malaria in India* in which he went with much detail into the methods employed by the malaria antiquarian in towns and country. The results of this work with many additions and with cooperation from numerous authorities were published after his retirement in a comprehensive volume entitled *Malaria in India*. This book not issued

until 1927 detailed the general history of malaria its geographical distribution in India its contributory causes prevalence and mortality. It furnished a very full history of the habits of Indian anopheline; this section of the work being supplied with a large quantity of admirable illustrations. The clinical history and diagnosis of malarial fevers and the various methods of prevention were all set out and among a group of appendices important matter was added bringing the subject up to date. The work was the outcome of much personal knowledge and great industry calling the attention of the economists and statesmen to the many sides of a menacing problem. Its production was a fine exploit during the closing years of a distinguished career.

Sir Patrick Hehir in addition to the distinctions enumerated, possessed the life-saving medal of St. John of Jerusalem, was a Knight of Grace of the Order and a F.R.S. Edin. He married in 1908 Dora a grand daughter of Edward Lloyd who founded the *Daily Chronicle* by whom he had one daughter. He was in his 78th year at the time of his death.

GEORGE PARKER M.D. Camb

We regret to announce the death of Dr. George Parker consulting physician to the Bristol General Hospital and a physician of distinction well known outside his immediate circle.

He was born at Claverdon Warwick the son of Mr. George Parker. He was educated at Stratford on Avon and St. John's College Cambridge where he had a successful academic career graduating as B.A. in 1877 with honours in the History and Moral Science Tripos. He was an assistant master at Rugby for a short period and then went to St. Bartholomew's Hospital for medical training. He graduated as M.D. Camb. in 1880 proceeding to the M.D. degree in 1881. He followed a post-graduate course in Vienna and held several resident appointments being medical officer to the Paddington Green Children's Dispensary and the Bristol Dispensary before going into practice in Clifton in 1887. He was appointed assistant physician to the Bristol General Hospital in 1892 and was a member of the staff until his retirement on seniority and election as consulting physician. He was an important member of the University of Bristol lecturing in particular on medical jurisprudence a subject in which he was at one an examiner at the University. He had marked literary gifts wrote a history of surgery in Great Britain showing his antiquarian knowledge and delivered the Thomas Vicar's lecture before the Royal College of Surgeons of England.

We owe to Dr. I. A. Burrell the following appreciation: During the years 1892-1893 of his association with the Bristol General Hospital as assistant and full physician his friendly personality endeared him to all with whom he came in contact—perhaps one would not say for forcefulness of character but rather for the frankness of his nature and approachability was he so liked. He was appointed to the visiting staff of the Bristol General Hospital in 1892 becoming full physician in 1901. He was president of the Association of Physicians when that body met in Bristol and of the Bristol Medical-Chirurgical Society in 1916. Being particularly interested in the various manifestations of chronic rheumatism and osteoarthritis he had charge of the

physiotherapy department of the hospital from 1901 until his retirement, doing much work, and making contributions to literature, upon these maladies. As a consultant he came to be regarded as always giving of his best, with a most likeable unaffected straightforwardness, and would spare no pains to do the utmost for the patients coming under his supervision, often, as the nature of their ailments so frequently required, for lengthy periods. For many years he had a very large following of outpatients, by whom he was greatly beloved for the individual interest and sympathy which he extended.

"Outside his work he was keenly interested in archaeology, and, since his retirement from the active hospital staff, went out on several occasions as medical officer to the Flinders Petrie Expedition in Syria. Of late years, too, he became greatly interested in the University medical library, acting as honorary librarian until his death. With great courage he persisted in his activities in spite of a progressing physical enfeeblement leading to the end. His death is a sad loss to many, his contemporaries and a host of others will retain affectionate memories of him."

JOHN DALLAS EDGE, C B, M D R U I, F R C S I

MAJOR GENERAL R.A.M.C.

THE death occurred on May 1st at his home in Dublin, at an advanced age, of Major General John Dallas Edge, whose military record was a remarkably fine one. He was born in 1848, the son of the late Joseph Edge of Timahoe, Queen's County, and received his medical education at the Meath Hospital, Dublin, graduating as M.D. R.U.I. in 1870. He entered the Royal Army Medical Corps at once and was attached to the 1st West India Regiment. The regiment was stationed at Orange Walk, British

Honduras, and shortly became the centre of a fierce little Indian revolt. The military commander was wounded, and young Edge took his place and successfully organised the defence, being specially promoted for gallantry. In the Zulu war of 1879 and in the second Afghan war which followed rapidly, Edge was again in the thick of the fighting, and for his work at Mawand and Kandahar he received the thanks of the Government of

MAJOR GENERAL EDGE

(Photograph by Elliott & Fry)

India. In 1882 he was serving in Lord Wolseley's expedition to Egypt, was present at Tel el Kebir, and was again a marked man for the value and bravery of his services. He received the Tel el Kebir medal with clasp and the Khedive's star. The outbreak of the South African war found Edge a lieutenant colonel and with that rank he accompanied Sir Redvers Buller's army to Natal. He was present at the battle of Stormberg and was responsible for removing the bulk of the wounded from the field in circumstances which required much and deter-

mined bravery. He was promoted colonel, awarded the C.B., and at the end of the war was appointed P.M.O. of the South African Command. On return home he became P.M.O. of the Irish Command and retired in 1908 on the age limit. At the outbreak of the European war he volunteered for service despite his seniority, and was placed in charge of the Queen Alexandra Military Hospital with the rank of major general, a post which he held until his second retirement in 1917.

Major General Edge married in 1890 Jane, daughter of John Ruskell of Arklow, Co. Wicklow, by whom he had one son. He had reached his ninetieth year

JOHN GALLETLY, M B, C M Edin

THE death occurred on April 10th of Dr John Galletly, well known in South Lincolnshire for his activities in the promotion of public health. He graduated as M.B., C.M. in the University of Edinburgh in 1886, having already studied at Marburg and at Vienna. He then went into practice in South Lincolnshire where he remained until his death 48 years later. In 1895 he took the D.P.H. Camb. and was appointed M.O.H. to the Bourne R.D., following on an inquiry into the sanitary conditions in those parts of Kesteven. Thanks largely to his persistent and patient endeavours the area was transformed from the worst to the best in the county. An isolation hospital was provided and new schemes for housing and water supply devised, so that when following the war, a progressive drive was made the ground was well prepared. Throughout Galletly by a fine example showed what the work of a part-time medical officer can produce when an independent spirit is backed by an intimate knowledge of the conditions and the people in his area.

We have received the following personal tribute: "A well grounded scholar in the humanities, Dr Galletly was fond of reading and of travelling. He was of the old school of general practitioner, hard working and finding his hobby in his work. He gave his best to his patients, never sparing himself and being always ready to take up the cudgels on their behalf when officialdom pressed. Impatient of humbug or conceit, he was loyalty itself to his fellow colleagues. He excelled in midwifery and had the art and knowledge and massive experience of a lifetime behind him, to help and guide and teach those that followed him. He was of a retiring disposition, but his integrity, kindness, and generosity made him the friend of all who came to seek help at his hands."

LUKE GERALD DILLON, O B E, M D R U I, M Ch

Dr Luke Dillon, who died on April 27th, was a son of Charles Blake Dillon of Springlawn, Co. Ros common. He received his medical education at Queen's University, Dublin, where he graduated as M.D. R.U.I. and M.Ch. in 1882. His career was spent largely in Seaham where he was at one time medical officer of health to the U.D.C. He was also surgeon to the Seaham Harbour Infirmary, Admiralty surgeon, and at one time surgeon to the Londonderry Collieries. He served during the war as a major, R.A.M.C. (T), and received the O.B.E. He was a man of wide interests, a F.S.A., and a J.P. for the county of Durham. He married Elizabeth Mary daughter of the Hon. Hubert Dormer, by whom he had one son. Dr Dillon had an interesting pedigree, being descended from Theobald Viscount Dillon, who was born in the Tower of London in

1591 and who in 1642 took the Oath of Association with the Irish Confederation. Dr Dillon had retired from the profession for some time before his death which occurred at Oxford.

HERBERT VICTOR HORSFALL M.B. Ch.B. Leeds

His death took place on April 18th of Dr Herbert Horsfall at the early age of 42. He was the son of the late Mr A. W. Horsfall of Halifax and received his medical training at Leeds University. He graduated as M.B. Ch.B. Leeds in 1917 and acted as house surgeon and resident surgical officer to the Leeds General Infirmary. During the war he served as medical officer to a combatant unit in East Africa holding the rank of captain. Thereafter he was in practice for a time at Cleckheaton after which he went into partnership in Otley. While at Otley he was actively associated with the Otley St. John Ambulance Association. He became medical officer to the New Hall Infirmary and held a high place socially in the Otley district. His death was unexpected as he was in the prime of middle life, but he had been in failing health for some time.

HENRY PRESCOT FAIRLIE, M.D. Glasgow

The death occurred at the end of March of Dr H. P. Fairlie the well known Glasgow anaesthetist. He was president of the section of anaesthetics of the Royal Society of Medicine 1933-34 and was a valued member of the council of the Association of Anaesthetists as well as of the editorial board of the *British Journal of Anaesthesia*. These offices had brought him into contact with many anaesthetists in London and the result had always been to establish in them warm feelings of friendship.

A contemporary writes: Fairlie a professional

excellence was accompanied by an unusual degree of modesty and charm. His text book written in elaboration of Ross's work was widely read and esteemed. He may well be regarded as one of the pioneers of modern anaesthetics in Glasgow. His example and his teaching did much to break down a traditional adherence to the routine use of chloroform and Fairlie fearlessly exposed the ill results which this practice had inflicted in the city where he practised. He contributed freely to the periodical literature of his subject and his writing was always free from padding and of practical value. His death is a severe loss to anaesthetics in general and leaves many English friends and colleagues the poorer.

JOHN LUKE JACKSON M.B. B.Ch. Belfast

The death occurred on April 5th of Dr J. L. Jackson medical superintendent of the Knowle Mental Hospital, Fareham. He received his medical training at the Queen's University Belfast and graduated with honours as M.B. B.Ch. Belfast in 1910. He showed early his interest in psychological medicine, and shortly after qualification was appointed as assistant medical officer to the Knowle Mental Hospital. At the outbreak of war he joined the R.A.M.C. and had an eventful military career seeing service in France and Gallipoli and receiving the Croix de Guerre. He had the unpleasant experience of being for a time a prisoner of war. On the cessation of hostilities he returned to his appointment at the Knowle Mental Hospital, and became medical superintendent in 1922. He was principal medical adviser to the Hants Joint Mental Health Institutions Committee and earned the reputation from all with whom he came into contact of being an energetic and sound administrator.

PARLIAMENTARY INTELLIGENCE

MILK PASTEURISATION

THE POOLE EXPERIMENT

In the House of Lords on April 22nd on the motion of Lord MAHER the Poole Corporation Bill was read a second time.

An Opponent of the Bill

Lord CRANWORTH moved that if he an instruction to the committee to which the Bill might be referred to strike out Clause 21 (by laws as to pasteurisation of milk). He said that this Bill raised a matter of grave national importance and he had always understood that a matter of general principle should never be brought forward in a private Bill. Such powers as were asked for in this Bill had never before been given or asked for in England. If Parliament granted such powers in this case it would seem logically impossible to refuse them in any other. The real reason for bringing Clause 21 into this huge Bill of 52 clauses was an outbreak of typhoid inournemouth 1901 and Christchurch. It was therefore admittedly panic legislation and for that reason somewhat to be deprecated. He had been at some pains to find out which milk really was responsible for that outbreak. The Poole corporation said it was but his local informants had told him that in his opinion it was not. The Dorset County Council were opposed to the Bill.

The main effects of pasteurisation were four: (1) It killed most of the obnoxious germs in milk. (2) It enabled dirty milk to keep for three or four days whereas otherwise it turned sour after about twelve hours—which was in itself rather a safeguard to the public. (3) It put out of action all small

producer-retailers because they had not the money to provide the necessary plant to do their own pasteurising. (4) Most important of all (he thought) it devastated the milk and destroyed some of its component parts. It remained a very good beverage, but it did not remain milk, and not such a good substance as milk, and that was the reason why another large section of the medical profession and a very much larger section of milk drinkers preferred raw milk.

If properly treated pasteurised milk was quite safe immediately after it had been pasteurised. But it was not always properly treated. Further pasteurised milk was subject to recontamination not only as quickly as raw milk but even more quickly. Generally speaking the reason for pasteurisation was said to be the prevention of tuberculosis. But many more people suffered and died from tuberculosis through not drinking milk at all than those who suffered from drinking bad milk. In the country districts where pasteurised milk was unavailable not only was there less tuberculosis but tuberculosis had gone down in a greater degree than in the towns.

The Diseases of Animals Committee said that if vitamin C was destroyed it could be returned by giving the children lime juice or orange juice. But their lordships think that in the poorer parts of our great cities the children were going to get orange juice or lime juice whenever they got a glass of milk. The loss in vitamin C through pasteurisation was first in vitamin C the loss of which causes scurvy, and secondly in vitamin D a loss which caused rickets. The chief medical officer of Dr Barnardo's Homes Dr A. H. Macdonald had made an exhaustive

study of this subject and had come to the following conclusions—

"(a) The child on raw milk is very fit (b) Chilblains are practically eliminated (c) The teeth are less likely to decay (d) The resistance to tuberculosis and other infections is raised (e) In one of his homes containing 760 delicate boys who were fed on raw milk for five years, only one case of non-pulmonary tuberculosis occurred, while in the preceding five years with similar types of children fed on pasteurised milk fourteen cases of non-pulmonary tuberculosis occurred"

There might be a case, said Lord Cranworth, for prohibiting the sale of unclean milk unless it had been pasteurised, but there was an equally good case, where clean milk was available, why it should not be pasteurised at all. The farmer had been asked to clean up his milk. He had been forced to spend large sums of money. He had been induced to have a new system, a higher grade of milk, and under the Accredited Scheme no fewer than 20,000 herds already participated. Were they going to take the retrograde step of saying that all this expenditure had been unnecessary, and say in effect "Produce as dirty milk as you like so long as you put it in the pasteurisation plant, when it will be just as good as the other"? Pasteurised milk could now be obtained wherever it was asked for. In Poole 80 per cent. got it. He could not see why people who disapproved of pasteurisation should be forced to do something which they believed to be to the harm of their children.

A very grave step was proposed in this clause. Surely if it was right, the Government should set up a committee—not a committee of producers or distributors, nor yet of doctors, but a committee of good common-sense people accustomed to weigh evidence—and ask them to present a report. Then let the Government, after consideration, produce the necessary legislation.

Case for Local Legislation

Lord MARKS said that anyone who had lived, as he had done, through the recent typhoid epidemic, when 900 people were affected and 51 died, would not imagine that the Poole corporation were doing anything panicky but were simply doing their duty in trying to ensure that such an epidemic should not occur again. Milk might be clean but not safe, and what the Poole corporation was seeking to do was to make the milk not only clean but safe. It had been suggested that they should put this off until the Government brought in a measure to deal with the whole community. If that were done, the Government would find themselves up against difficulties that they were not up against in this Bill. What might be done easily for a municipality with 500,000 people would be a very difficult and doubtful thing to do for a village with 200 or less. Their lordships had already given a Second Reading to the Glasgow Corporation Bill which contained a similar clause. There was no petition to the House against it, and no memorials against it, but 44 municipalities in England and Scotland had sent to the Ministry of Health memorials and petitions in favour of Clause 21 of this Bill, which it was now said should be deleted.

A Government Bill Promised

Viscount HALIFAX, Lord Privy Seal, speaking for the Government, said that the report of the Economic Advisory Council's Committee on Cattle Diseases, presided over by Sir Gowland Hopkins, made certain recommendations which did not correspond with the proposals in the Bill promoted on behalf of Poole. He understood that if this Bill received a second reading in its present form it would be referred to a Select Committee of the House so that the proposals as to pasteurisation might be specially examined. In the Government's view such an inquiry would be unsatisfactory and probably inconclusive. Such an inquiry ought not to be held in connexion with any

particular locality, for the question was general, affecting the country as a whole. The Government's intention therefore was to bring forward long-term legislation dealing with general milk policy in the near future. In that connexion the question of pasteurisation would be examined in the light of all the evidence available. When the proposals were brought forward Parliament would have opportunities for examining them in a form more satisfactory than was open to it at the present time. There was no reason for supposing that in the absence of compulsory pasteurisation the people of Poole would be in any different position as regarded the possibility of infected milk from that of persons in any other part of the country. Therefore, pending general legislation, there seemed to be no necessity to make special provisions in the case of Poole in order to prevent a recurrence of the outbreak the town had experienced.

The Earl of ONSLOW (chairman of committees) said he did not think it would be fitting to hold a long inquiry by a Select Committee into the question of pasteurisation, which had already had so many committees sitting on it. In the absence of any special necessity in Poole, the matter might safely be left to be dealt with by Public Bill.

Lord Dawson's Speech

Viscount DAWSON OF PENN said that the Poole experiment would have been very valuable. No indication had been given as to how long it would be before a general measure came before them. This matter had been under consideration for the whole of the century, and the position was really grave. Lord Cranworth was confusing clean and infected milk. Milk might be perfectly clean and yet be infected. On the other hand it might be uninfected and yet not be clean. He entirely agreed with Lord Cranworth that if pasteurisation was not to be efficient it would be better not to have it at all. But here was no question of using pasteurisation except effectively, and there was an overwhelming body of evidence that if it was carried out effectively pasteurisation prevented the conveyance of certain infectious diseases.

The mortality from tuberculosis had steadily declined, but there was one blot on the picture—namely, that there had not been the same improvement in the bovine type of infection as in the human type. In 1931 in this country there were 6000 fresh cases of milk tubercle, with 2600 deaths—a perfectly needless death-rate. It had to be remembered that milk tubercle attacked not only the weaklings, but also the strongest children, therefore they were wasting 2000 children that need not be sacrificed. In Scotland, for the same year, there were 1000 children affected and 465 deaths. By not dealing with this matter they were continuing this death-rate. There was a satisfactory movement for extending the supply of milk to children. But this made it doubly important to see that the milk-supply was clean and free from infection. He entirely agreed that it must be made clean. It would be the duty of the medical officer of health of Poole to see that it was clean. But the worst of this tubercle was that tuberculosis in cattle might occur in apparently healthy cows. The Department of Health in Scotland took the churns which went into one city and found that 10 per cent. of the samples contained not dead but living tubercle bacilli, so that every time a child drank a glass of milk—a child at its most susceptible age—it was likely to be imbibing tubercle bacilli. In Glasgow, over 13 per cent. of the samples contained living bacilli, and therefore each glass of milk was an active source of infection to the children. Mention had already been made of the Bournemouth outbreak, and the deplorable number of deaths which occurred. There were others. It might almost be asked, in the words spoken of Pharaoh "How much persuasion does he require to let the people go?" In Brighton and Hove there was an outbreak in

1020 of septic sore-throat due to milk infection subsequently to its being withdrawn from the cow. A thousand families were affected, and there were 65 deaths. Then there was the Epping epidemic of paratyphoid in 1931 with 260 cases and there was the famous Chelmsford epidemic of scarlet fever and sore-throat, in 1935 with its 1000 cases, and then followed this Bournemouth outbreak. Therefore it must be realised that milk might be perfectly clean and still be infected owing to handling subsequently to being milked from the cow. He was bringing this matter forward really to stress the urgency of this problem—that if it was not desirable to allow Poole to work this out on a small scale and prove it, yet it was an urgent matter which should be brought to an issue.

If they could secure that milk should be controlled and that herds should be perfectly healthy, that would be the ideal way of dealing with this question, but it was impracticable except in a few selected spots. The expense of making good all the tuberculous cows in this country was one that no reasonable Government could face. For these reasons therefore protected herds could only be few in number and could be maintained only where conditions were very favourable. In Denmark they did allow raw milk to go to children, but for the rest of the population they insisted on milk being pasteurised. But the raw milk that went to the children—less than 20 per cent. of the total—had to go to specially controlled dairies. A further reason for pasteurisation was that even when milk was free from tubercle bacilli it was still liable to get infected by handling. The Bournemouth Epping and Chelmsford epidemics were all due to infection reaching the milk after it was taken from the cow. That was why he saw no alternative to a properly organised system for pasteurising milk. He sympathised with the one-sixth of the milk producer-salesmen in the country who would suffer. It would be a change for them to have to pasteurise the milk, but they could imitate Denmark and go in for co-operation. Or if necessary they should be compensated. The price would be a very small one to pay. He could not see what good it was to spend vast sums on health services and leave this bad sore open year after year.

In conclusion Lord Dawson said he very much regretted that this experiment could not be made in Glasgow and in Poole so that when the Government came to consider their more general legislation (and they had no information as to when that would be) they would have gained some experience.

The Debate Concludes

Lord STRABOLOT said that the Medical Committee which advised the London County Council were very anxious that the powers in Clause 21 should be given to the Poole corporation. When were they to expect this legislation of the Government? He understood that the time-table was already overcrowded. They had had a great deal of talk recently about malnutrition and the health of the population; they had a special committee to consider how to improve the physical fitness of the people; and here was an attempt to stop at its source a cause of sickness and death. Yet Lord Halifax said they must wait until the whole matter had been examined once more and a general Bill was introduced for the whole country.

Lord CROMWELL wished to correct any impression that the House generally accepted the principle that pasteurisation must come sometime and that the only issue at this stage was whether it should be introduced through a local authority or by the Government. He regarded the pasteurisation of milk as a very doubtful cure at its very best.

Lord MARRAS said that if the Bill were taken as an opposed Bill it would entail considerable expense. The Poole corporation would be satisfied for it to pass with the instruction to the committee that Clause 21 should be deleted.

The motion to delete Clause 21 was agreed to.

MATERNITY SERVICES IN SCOTLAND

In the House of Lords on April 27th Lord STRABOLOT and MOUNT ROYAL moved the second reading of the Maternity Services (Scotland) Bill. It covered he said a wider field than the English Midwives Act of last year. Scottish medical men took a much larger part in midwifery practice than their English confrères and the Bill was therefore not limited to a midwife service only. It proposed that any woman who desired to be confined in her own home would be entitled to the services of a midwife and a doctor. If the need arose the doctor could call for the advice or help of an obstetrician of recognised standing. A thorough system of antenatal and postnatal care would be a fundamental feature of the scheme. Local authorities would be free to select the type of arrangements they preferred so long as the services were adequate. In some areas medical arrangements—other than those relating to obstetricians—might be made with all general practitioners in the area who were willing to take service on the terms offered. In other areas the antenatal and postnatal examinations might be carried out at the authority's clinics, and arrangements made either with all practitioners or with a limited number of them to provide the intranatal service. No insuperable difficulty was anticipated in securing the services of qualified obstetricians in most areas, but adjoining areas might sometimes find it desirable to combine for the purpose. The local authorities were required to consult with any local organisation representing the medical practitioners in the area before submitting their proposals for the Department's approval. The remuneration of midwives and doctors participating in the service would be a matter for negotiation between them and the local authorities. One of the beneficial aspects of the scheme would be the elimination of bad debts which had been a source of much worry particularly to midwives.

Clause 6 the object of which was to prevent the attendance of unqualified persons on women in childbirth contained a proviso exempting from the prohibition medical students and pupil midwives attending as part of their course of training. It has been expressed about this permission but the department was assured that the arrangements for training in every Scottish university were such as to ensure the safety of the patients. It was clear that neither medical students nor pupil midwives were sent out to the homes of the people until they had been properly tested in the maternity ward and had satisfied their teachers that they could be trusted with outside cases.

Lord STRABOLOT welcomed the Bill which he said was a very long step towards a State medical service. It was a very much larger step than was contemplated for England and he congratulated the Scottish Office upon its courage in introducing the Bill.

The Bill was read a second time.

NOTES ON CURRENT TOPICS

In the House of Lords on May 14th the Hydrocyanide (Fumigation) Bill on the motion of the Marquess of DUFFERIN and ARA was read the third time and passed. On the same day the Maternity Services (Scotland) Bill passed through committee without amendment.

In the House of Commons on May 14th Sir ERIC LEE, M.P., Minister of Health introduced the Local Government Superannuation Bill in order to make further and better provision with respect to the payment of superannuation allowances and gratuities by local authorities and certain statutory undertakers, and with respect to the persons entitled to participate in the benefits of a local authority's superannuation fund or scheme. The Bill was read a first time.

QUESTION TIME

WEDNESDAY, APRIL 28TH

Mouthpieces of Public Telephones

Colonel GOODMAN asked the Postmaster General what action was taken to cleanse the mouthpieces of the instruments in public telephone boxes, and at what intervals—Sir W. WOMERSLEY, Assistant Postmaster General, replied: The mouthpieces and earpieces of telephones in call offices provided with an attendant are wiped with a clean cloth moistened with suitable disinfectant every morning. At other call offices the frequency depends on the location of the kiosk and the extent to which it is used.

Colonel GOODMAN: If no official is handy are these call offices' mouthpieces ever disinfected?

Sir W. WOMERSLEY: A full investigation has been made into this question by a committee upon which medical men sat and their decision was that the infection was more psychological than actual. (Laughter.)

Mr. THORNE: Can the hon. Member give any guarantee that everybody's mouth is clean before using the telephone?

Sir W. WOMERSLEY: I will leave that to my hon. friend.

THURSDAY, APRIL 29TH

The Birching of Juvenile Offenders

Mr. SHORT asked the Home Secretary if he was aware that a further six boys were ordered to be birched by the West Riding juvenile court, Doncaster, on April 21st, whether the sentences had been carried out, and whether he would now reconsider his decision not to advise magistrates not to impose such sentences having regard to the appointment of the committee of inquiry—Sir JOHN SIMON replied: Yes, Sir. Six boys were ordered on April 21st to be birched, five have been birched and the police surgeon found that the sixth was unfit for the punishment. I cannot do more than say that I am sure that justices will realise that I regard the whole subject as one which needs investigation.

Mr. T. WILLIAMS: Is the right hon. gentleman aware that the boy who was not fit to be birched on the day when the other five were birched has been invited to attend the police court on Tuesday next to be birched? Does the right hon. gentleman regard it as consistent with the law for a boy to be sent home and be called upon to return a week later to receive his birching?

Sir J. SIMON: I do not know the circumstances to which the hon. Member refers but will make inquiries.

Mr. SHORT: Would the right hon. gentleman send a circular to clerks of the peace calling their attention to the fact that he has set up this committee of inquiry?

Sir J. SIMON: I could not do that, the fact is perfectly well known, and I think that when an inquiry has been set up it is very essential that the authorities should not seem to pronounce judgment before the inquiry is completed.

Training of Blind Children

Sir WILLIAM JENKINS asked the President of the Board of Education if he had any record of the number of blind boys and girls who, on leaving school, were being trained for some trade or any other occupation, and the number of these wholly employed for the years 1935 and 1936 in England and Wales, separately—Mr. OLIVER STANLEY replied: It is estimated that at present the number of blind boys and girls as distinct from the partially sighted who leave the schools for the blind each year at the age of 16 is about 200. The Board do not have a statistical record but it is known that practically all of these who are likely to be employable enter vocational courses of training. On March 31st, 1936, the total number of boys and girls from schools for the blind who were being trained was 993. The Board have no statistics concerning the employment of the blind, which is a matter for my right hon. friend the Minister of Health.

Sir WILLIAM JENKINS asked the President of the Board of Education what was the number recorded of borderline cases of pupils in schools for the blind, and was the test for certification of blindness causing a hardship on certain types of children who were educationally blind, but on reaching a certain age were marked sighted for

industrial purposes—Mr. OLIVER STANLEY replied: The Board have no statistical record of the number of such cases, but I agree with the conclusion of the Committee on Partially Sighted Children that such children should be taught in schools or classes for partially sighted children and that hardship is involved if they are educated and brought up as blind and have later to enter the sighted world, for which their education has not fitted them.

Hospital Arrangements in Staffordshire

Mr. MANDER asked the Minister of Health the present position with regard to the protests against the arrangements made by the Staffordshire County Council in Wednesfield, Willenhall, and other districts for the treatment of invalids and old people, and whether he would endeavour to arrange that negotiations should be reopened between the Staffordshire County Council and the Wolverhampton Borough Council, with a view to arrangements being made for Wednesfield and Willenhall residents to have the same facilities for obtaining treatment at the New Cross institution as were possible prior to April 1st, 1937—Sir KINGSLEY WOOD replied: I would refer the hon. Member to the answer which I gave to his question about these arrangements on April 8th. I am in communication with the county council regarding the representations which I have since received on this subject and will inform him further of the position when I have received their reply.

Mr. MANDER: Will the right hon. gentleman bear in mind that there is still plenty of room in the New Cross institution where invalids can go in a few minutes instead of having to travel 14 miles to Wordsley?

Sir K. WOOD: Yes, Sir.

Old Age Pensioners in Poor-law and Mental Hospitals

Mr. LEACH asked the Secretary to the Treasury if he had considered the copy sent to him of a resolution of the Eastbourne pensions committee, and supported by other committees, asking for a reform of the old age pensions law so as to provide a fairer method of calculating the means of persons who had been inmates of poor-law institutions or mental hospitals, and if he was prepared to comply with the wishes so expressed—Lieut. Colonel COLVILLE replied: The resolution to which the hon. Member refers is presumably that which asked that the cost of maintenance should be excluded in calculating the means of a pensioner who is in a poor-law institution for medical or surgical treatment and that the disqualification in certain circumstances from receipt of pension of a person in a mental hospital should be removed and the cost of his maintenance there disregarded in calculating his pension. This would have the effect of giving the pensioner free maintenance as well as a pension calculated on the basis that he is maintaining himself, and in so far as the pension is appropriated by the local authority, it would operate merely as a grant in aid of local expenditure. I am afraid, therefore, that the Government are not prepared to introduce the legislation which would be necessary to effect these changes.

Mr. LEACH: Is it not reasonably argued that old age pensioners who need medical or mental treatment of that sort are in such poor conditions and circumstances that they should have this concession made by the Government?

Lieut. Colonel COLVILLE: I have given the hon. Member a long and careful answer and I am afraid I cannot add to it.

MONDAY, MAY 3RD

Health Insurance and Maternity Benefit

Mr. DE ROTHSCHILD asked the Minister of Health whether he would introduce legislation to amend the National Health Insurance Acts so as to increase the amount of maternity benefit payable by approved societies seeing that the Midwives Act 1936, by making compulsory the attendance of a qualified midwife at all confinements, threw an added financial burden on insured contributors at such times—Mr. HUDSON, Parliamentary Secretary to the Ministry of Health, replied: The position of a woman entitled to maternity benefit as regards the arrangements for attendance at her confinement is not materially affected by the provisions of the Midwives

Act 1936 The National Health Insurance Acts have always contemplated that such a woman should be attended either by a medical practitioner or a qualified midwife. Moreover the Midwives Act expressly provides that the fees charged by local authorities for the services of their midwives may be remitted in whole or in part where the circumstances justify such remission. My right hon friend does not therefore, consider that the coming into operation of the new Midwives Act affords any reason for the suggested amendment of the National Health Insurance Act.

TUESDAY MAY 4TH

Prevention of Silicosis

Mr JAMES GRIFFITHS asked the Secretary for Mines the precise nature of the preventive measures that had so substantially reduced the incidence of silicosis in the Rand mines whether these preventive measures were made obligatory upon the Rand mine-owners by statute or regulations; in how many collieries in Great Britain and South Wales respectively these preventive measures were in use; and whether he proposed to issue the regulations to make their adoption obligatory upon the mines of this country.—Capt CROOKSHANK replied: In South Africa those mines which are scheduled under the Miners' Phthisis Benefits Law are subject to regulations requiring special preventive measures to be taken. I cannot within the limits of an answer state those preventive measures precisely but the general purport is to provide for initial and periodical medical examination of persons exposed to the risk and for the suppression of harmful dust which might be breathed by such workers. I have not sufficient statistical information to enable me to answer the third part of the question. As regards the fourth part the South African regulations apply only to the scheduled mines which generally I understand, are the metalliferous and not the coal mines; and as at present advised I do not propose as regards the coal mines of this country to displace the method of differentiating requirements according to risk in favour of applying the same requirements to all these mines. The whole matter is however under consideration by the Royal Commission now sitting.

Maternal Mortality

Mr GEORGE GRIFFITHS asked the Minister of Health the number of deaths in childbirth for 1936 and the number of deaths arising out of childbirth for 1936.—Mr HUDSON Parliamentary Secretary to the Ministry of Health replied: For 1936 the deaths classified to pregnancy and childbirth were 2302 while the deaths not classified to these causes but returned as associated therewith were 677. These figures relate to England and Wales, and are provisional.

Typhoid Fever in Liverpool

Mr GROVES asked the Minister of Health how many cases of typhoid fever had been notified at Liverpool this year and whether this outbreak was now at an end.—Sir KINGSLEY WOOD replied: 123 cases of typhoid fever (including paratyphoid) have been notified in Liverpool during the present year up to April 24th the majority of which occurred in an outbreak of paratyphoid fever in January. I am informed that that outbreak is regarded by the local authority as being now at an end.

Employment of Boys in Coal Mines

Mr TENNER asked the Secretary for Mines how many boys there were under 16 years of age working underground in coal mines that come under his department.—Capt CROOKSHANK replied: At Dec 12th 1936 the latest date for which the information is available 17,044 boys under 16 years of age were employed below ground in coal mines in Great Britain.

Experiments on Living Animals

Mr LEACH asked the Home Secretary how many inoculations had been performed in contravention of the Cruelty to Animals Act 1876 by the experimenter referred to in the Home Office Return of Experiments on Living Animals for 1935 and what period of time had been covered by the illegal inoculations.—Mr GEORGE WOOD Under-Secretary Home Office replied: 14 and all were given on the same day.

THE LANCET 100 YEARS AGO

May 13th 1837 p 264

FROM THE EVIDENCE RELATING TO THE MEDICAL RELIEF OF THE SICK POOR IN THE PAROCHIAL UNIONS given before the SELECT COMMITTEE OF THE HOUSE OF COMMONS in 1837 Tenth Day Wednesday April 14 Mr Fazakerley in the Chair

MR. THOMAS BOURNE.

4324 Examined by the Chairman] You are master of the Farham workhouse?—Yes

4328 In what state were the boys Cooke, Warren, and Withers, when they were sent to you?—They appeared healthy

4330 Who is the medical man of that house?—Mr John Blatherwick

4332 Had those children dirty habits?—They commenced their dirty habits the first or second night after their admission

4334 What observation did the medical man make upon hearing of that?—None in particular

4336 What did you do to correct those habits?—With held part of the food

4342 Were the visiting guardians made acquainted with the food being diminished?—Yes they did not object to it Half of the food for the day was stopped

4348 Was any punishment also had recourse to?—The children were placed in the stocks frequently both standing and sitting and were kept in them from meal to meal at the same time that their food was diminished I believe. When the schoolmistress intimated to me that it did not appear to have any effect upon their filthy habits, I desired her to discontinue withholding their food or any other punishment

4350 How soon after they were in the house did the schoolmistress observe to you that their health appeared to decline?—I suppose a month

4630 Will you read the dietary of the workhouse for young children?—On the Sunday children under nine years of age have three ounces of bread for breakfast and one pint of gruel with milk. The dinner is one pint of meat soup half a pound of potatoes and three ounces of bread; supper four ounces of bread, one ounce of cheese or half an ounce of butter. Monday for breakfast five ounces of bread one pint of gruel with milk. Dinner eight ounces of meat pudding; supper five ounces of bread one ounce of cheese or half an ounce of butter

4641 On Monday were these children almost always deprived of half that sustenance?—The Monday was the same as any other day; they were not punished more than twice or three times a week. (The dietary of the other days in the week was detailed by the witness)

4643 By Mr. MILLER] Are the Committee to understand that with this dietary those dirty children were punished frequently three times a week by half that allowance being stopped?—Yes

4645 Give the number of ounces of food for the whole week?—2380; nine ounces of which is meat; potatoes 32 ounces; cheese 7 ounces; pudding 8 ounces; three pints of soup; and a pint of gruel every morning

4689 By Mr. MILLER] You received back one half of the allotted food of the diminished meals of children?—Yes

4691 What is done with it?—It is put up for the next meal

4696 Is it at the discretion of the mistress to withhold food as a punishment?—Yes and also to put children in the stocks

4717 You have stated that the children were taken to an out-house; is it a room or a stable or a wash-house?—It is a plastered room on the other side of the yard originally intended for a workshop with a stone floor

4720 Is there any fire place in it?—No

4722 At what period of the year were the children confined in that room?—In January

* * Oliver Twist was first published in 1837 in Bentley's Miscellany —T. D. L.

ROYAL SOCIETY CONVERSAZIONE

AMONG the exhibits at the Royal Society's conversation on May 4th was one by Prof H H Woollard, who showed radiograms of lymphatics made opaque by injection of thorotrast and barium. They demonstrated the longitudinal pattern of the vessels in the extremities and the circular arrangement around the trunk. The lymphatics above were seen to converge on the axilla and those below on the groin, the dividing line being about the middle of the trunk. The injection of lymphatics near a carcinoma showed that normal lymphatics traverse the mass, that many lymphatics about the carcinoma remain patent and contain no carcinomatous cells. Normal lymphatics pass from the growth to lymph glands found to contain metastases, it was concluded that carcinomatous cells occasionally rupture into a lymphatic vessel and are carried as emboli to the gland. Injections of thorotrast into the living had been used to investigate lymphatic oedema and obstruction, and also the lymphatic flow in skin transplantation and pedicle grafting. This part of the work had been done in co-operation with Sir Harold Gillies. Recently another opaque material which contained no thorium had been devised for injection.

Mr F C Bawden and Mr N W Pine of the Rothamsted Experimental Station and the department of biochemistry, University of Cambridge, showed some of the peculiar physical properties of nucleoproteins obtained from virus infected plants. These proteins are believed to have the largest molecules yet known, the molecular weight being of the order of 17,000,000. They are obtainable only from infected plants and are capable of transmitting the disease even in extremely high dilutions (1 in 10^{10}). They are prepared from the plant by solution and precipitation, the precipitate is dissolved again and the final material bears a quantitative relation to its infectivity. It is specific in its relation to the plant and, when injected in great dilution into rabbits, can produce antigens. Another exhibit, by Mr J D Bernal and Dr I Fankuchen, was of the X ray pictures of this protein in various states. The molecules had been shown to be rod shaped with a cross section diameter of 15μ but with lengths probably greater than 100μ .

During recent years several substances having growth promoting properties have been isolated from plants. Three, called auxin a, auxin b, and hetero auxin, are now recognised, the last being β indolyl acetic acid, a substance which has been synthesised. It is only known to promote growth in plants. It was the object of an exhibit by Imperial Chemical Industries Ltd. When painted on one side of seedlings grown in the dark it caused them to grow crookedly from overgrowth of that side, when applied to tomato plant stalks it had induced root formation quite high on the plant, when put on cuttings it was found to assist the vigorous formation of rootlets.

Lieut Colonel A J Peile showed the dart-like radula of a mollusc which lives in the Indian Ocean, the animal uses them for injecting a poisonous substance into its prey but occasionally, it is said, the poison has caused paralysis and even death in man.

Other exhibits were of models of protein molecules, including ones for pepsin and insulin (Mrs Dorothy Winch, D.Sc.) and modifications of dominance in mice (Prof R A Fisher and Mr K Mather, Ph.D.), while for the delight of the curious there were bells which sounded when touched with solid carbon

dioxide, human teeth fluorescing in ultra violet light, and earphones with which to listen to beetles in timber.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg Comdrs A de B Joyce and W G C FitzPatrick to President for Medical Department

Surg Comdr (D) S E Brown to Resource

Surg Lt Comdr (D) E R Longhurst and Surg Lt (D) W R Knott to Caledonia

The following have been appointed Admiralty Surgeons and Agents —

Mr B E Hawkins (Anerley road, S.E. 20) for London District No 8 (Catford, Dulwich, &c.), Mr F A Anderson (Stranraer) for Stranraer, Mr F E Higgins (Sudbury, Suffolk) for Sudbury, Mr J Cullen (Northampton) for Northampton, and Mr A C Ainsley (West Hartlepool) for West Hartlepool.

ROYAL NAVAL VOLUNTEER RESERVE

Surg Lt Comdr (D) G P Monk placed on the Retd. List

L F Donnan entered as Proby Surg Lt

DEATHS IN THE SERVICES

The death occurred on April 29th of Lt. Col. **FREDERICK JOSEPH GARLAND**, D.S.O. R.A.M.C (ret.) of Lydd. He was the son of the late James Garland of Rathmines Co. Dublin who was born in IR and was educated at the Royal University of Ireland and qualified M.B. in 1901. He joined the R.A.M.C. in January 1901 and became captain in July 1907. For a time he was at Ahmadnagar Military and then at Colchester. He served in the 1 greyhound War 1914-18 was mentioned in despatches and in 1918 was created D.S.O.

Vickers M B Sheff Denis John Williams M D Manch
and Reginald Alexander Wilson M D McGill

Licences to practise were conferred upon 212 candidates (193 men and 19 women) who have passed the final examination of the Conjoint Board and have complied with the by laws of the college. The following are the names and medical schools of the successful candidates —

[illegible]

F. Vernon, Manch. F. H. Volland, Birn. G. M. Ward, Lond. S. Ward and R. W. Watts, Camb. and St. Thomas's. G. V. Webster, Birn. T. Werner, St. George's. R. A. White, St. Bart's. E. H. L. Wigram, St. Thomas's. O. G. R. H. Williams, Oxon. and Westminster. S. I. Williams and A. D. Willis, Guy's. I. A. Winer, Middlesex. F. A. J. Woodland, Guy's. E. Wooll, Univ. Coll., and A. S. Woolstone and R. O. Yerbury, Guy's.

Diplomas in tropical medicine and hygiene were conferred (jointly with the Royal College of Surgeons) upon the following:—

H. Akhtar, S. Amarasinghe, R. H. Barrett, A. H. Booth, J. W. Bowden, J. C. Busby, K. L. Buxton, Dorothy G. Cowie, G. H. Fisk, A. B. Gilroy, S. A. Hasib, A. D. Hodges, W. H. Jeffrey, A. Mizrahi, P. P. Murphy, V. T. Pasupati, M. G. Pearson, C. Ponnambalam, J. D. Prasad, J. T. Robinson, M. Roushdy, C. A. Rumball, A. G. Rutler, S. Shrikhande, L. M. de Silva, M. Singh, D. W. Soman, A. S. Syed, A. L. F. Thomson, G. I. Watson, and J. G. Webb.

Lord Dawson was re-elected representative of the college on the governing body of the British Postgraduate Medical School and Dr Archibald Malloch the representative at the celebration of the fifteenth anniversary of the founding of the College of Physicians of Philadelphia on May 14th. Dr Edwin Bramwell will deliver the Croonian lectures on clinical reflections upon muscles, movements, and the motor path at the college at 5 p.m. on May 25th, 27th, and June 1st.

Society of Apothecaries of London

At recent examinations the following candidates were successful:—

Surgery—A. A. Beazeley, Guy's Hosp., N. Blackford, Univ. of Camb. and Middlesex Hosp., P. H. Denton, Guy's Hosp., S. M. M. Niall, Royal Colleges Edin., and W. G. Tillman, Guy's Hosp.

Medicine—P. H. Denton, Guy's Hosp., G. Howell, Welsh National School of Medicine, L. W. La Chard, St. George's Hosp., J. F. Mason, Univ. of Calcutta and London Hosp., A. P. Motley, Royal Colleges Edin., and F. L. Skinner, Univ. of McGill.

Forensic Medicine—P. H. Denton, Guy's Hosp., G. Howell, Welsh National School of Medicine, L. W. La Chard, St. George's Hosp., J. F. Mason, Univ. of Calcutta and London Hosp., A. P. Motley, Royal Colleges Edin., and F. L. Skinner, Univ. of McGill.

Midwifery—D. R. Daniel, Middlesex Hosp., J. B. Good, Guy's Hosp., J. F. Mason, Univ. of Calcutta and London Hosp., and F. D. Pitt Palmer, Middlesex Hosp.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery:—

N. Blackford, S. M. M. Niall, P. H. Denton, F. L. Skinner, and L. W. La Chard.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on May 3rd, with Prof. Archibald Young, the president, in the chair, the following were admitted to the fellowship: Joseph Alexander Bell (London), Hatimhai Shaikh Abduljally Malik (Bombay), and George Broughton Smart (India).

National Hospital, Queen square

The Lord Mayor, Sir George Broadbridge, took the chair on April 27th at a festival banquet given at the Mansion House in aid of this hospital. The guest of honour was the Duke of Kent, who made a moving speech describing the work of the hospital and its great needs. It was he said the oldest and largest hospital for nervous diseases in the world. The speed at which life was lived nowadays made a great toll upon everyone's reserves of nervous energy and caused many forms of illness. The hospital had a special claim on those interested in the industrial life of the country. Every step forward in science and mechanisation produced a new source of nervous strain for the workers. Leaders of industry, who had been generous in the past in providing money for research into the application of science to business, would not be deaf to an appeal on behalf of research into the causes and cure of nervous diseases due to the increase of scientific methods in industry. The Rockefeller Foundation would give £120,000 to the new research department if a like sum were raised in this country. The British people could not fail to take up that challenge. Sir Walter Monckton, K.C., supporting the toast, gave figures for the work of the hospital: 1500 in-patients with 300 operations a year. The hospital played he said, for a great part in the propagation of British methods, for 4200 British doctors from all over the world had studied

there in the last ten years. A film was then shown illustrating the activities of the hospital and the difficult conditions which the obsolete buildings imposed upon the workers. The amount realised by the appeal at the festival dinner came to about £25,000.

University of Manchester

The Rockefeller Foundation have made a grant of £5000 to be spread over four years, in support of the research work in biochemistry being carried out at the university under the direction of Prof. Heilbron.

Royal Medico-Psychological Association

The examination for the Gaskell gold medal and prize and the examination for the certificate in psychological medicine, will be held at the Maudsley Hospital, London, on May 26th and 27th. Further information will be found in our advertisement columns.

South-West London Medical Society

The meeting of this society which was to have been held on May 12th has been postponed until May 19th, when Dr Wilfrid Sheldon will read a paper on abdominal distension in children. The meeting will be held as usual at the Bohnsbroke Hospital at 9 p.m.

Gresham College

Four lectures on physics will be delivered at the College, Basinghall-street, London, E.C., by Dr J. Alison Glover on May 10th, 11th, 13th, and 14th at 6 p.m. He will speak on some aspects of the school medical service and the lectures will be open to all without fee.

West Kent Medico-Chirurgical Society

The annual dinner of this society will be held at Chiesmans Restaurant, High-street, Lewisham, S.E., on Thursday, May 20th, at 8 p.m. Dr H. V. Morlock will be in the chair. Tickets may be had from the hon. secretary, 267, Baring road, Grove Park, S.E. 12.

City of London Hospital for Diseases of the Heart

Queen Mary opened the new surgical wing of this hospital on April 29th. The accommodation includes ten single bed wards specially designed for serious chest operation cases. Patients in these wards will be selected irrespective of whether they are paying patients or not.

Palmer Memorial Hospital, Jarrow

This hospital, which has been in danger of closing down, now has its continuance assured. It owed a sum of money, consisting of loan and interest, amounting to £2875 to Palmer's Shipbuilding and Iron Company, but with the consent of the debenture holders and the High Court this has been cancelled.

Fellowship of Medicine and Post-Graduate Medical Association

The following courses have been arranged to take place during the latter part of May, and during June: thoracic surgery at the Brompton Hospital (May 24th to 29th); urology at St. Peter's Hospital (May 31st to June 12th); gynaecology at the Chelsea Hospital for Women (June 14th to 26th). Week-end courses will be held as follows: physical medicine at the St. John Clinic and Institute of Physical Medicine (May 22nd and 23rd); children's diseases at the Princess Elizabeth of York Hospital (May 29th and 30th); general medicine at the Prince of Wales Hospital (June 5th and 6th), and general surgery at the same hospital (June 19th and 20th); obstetrics at the City of London Maternity Hospital (June 12th and 13th). A clinical and pathological M.R.C.P. course will take place at 8 p.m. on Tuesdays and Thursdays at the National Temperance Hospital (June 1st to 17th). Other M.R.C.P. courses include chest diseases at the Brompton Hospital (twice weekly at 6 p.m. June 7th to July 13th), heart and lung diseases at the Victoria Park Hospital (Wednesdays and Fridays at 6 p.m. June 9th to July 3rd), neurology at the West End Hospital for Nervous Diseases (June 21st to July 3rd). Detailed syllabuses of all courses can be had from the secretary of the fellowship at 1, Wimpole street, London, W. The annual dinner-dance of the fellowship will take place at Claridge's Hotel, on Friday, May 28th.

The Central Council of Recreative Physical Training should in future be addressed at Abbey House Victoria street London SW 1

Merseyside Medical Practitioners Association

At a recent conference of medical practitioners held at the Liverpool Medical Institution the aims and objects of this association were unanimously approved and the support of its work was recommended (see *THE LANCET* April 24th p 1006)

National Institute of Industrial Psychology

Under the Heath Clark bequest three lectures under the general title of time and movement study will be given at the London School of Hygiene and Tropical Medicine Keppel-street W C at 5.30 p.m. on Mondays May 24th 31st and June 7th. The lecturers will be Mr G. H. Miles D.Sc. formerly director of the Institute, Miss A. G. Shaw investigator to the Metropolitan Vickers Electrical Company and Mr J. A. Edgell investigator to the Institute.

Royal Institute of Public Health

The council of this institute have awarded the Harben gold medal to Sir Gowland Hopkins O.M. F.R.S. professor of biochemistry in the University of Cambridge. The medal is awarded triennially to the person who in the opinion of the council has rendered the most eminent services to public health. Past recipients include Louis Pasteur, John Simon, Max von Pettenkofer, Lister, Koch, Metchnikoff, Behring, Roux, Ronald Ross, Sherrington, and Kitasato.

Treloar Hospital and College

On April 30th the trustees of the Lord Mayor Treloar Cripples Hospital and College at Alton entertained the honorary medical board to dinner at the Barbours Hall. Colonel Frederick Lawson, the chairman, said that eight years had passed since the last occasion of the kind and spoke of the appropriateness of meeting in the City. One lord mayor, Sir William Treloar, was the founder and inspirer of the work; another Sir William Dunn had acted as treasurer; and many of their successors had recognised their paternal duties. The work of the medical board he continued had expanded since the definition of cripple had been extended to almost every kind of disability, and the devotion of its chairman, Mr O. L. Addison for all these years is beyond any power to describe. The first of the board's two functions was to put the ideas of Sir Henry Gauvain, the medical superintendent before the trustees—ideas that had won the hospital a world-wide reputation. Their second function was to engage in the actual work of the hospital and Colonel Lawson expressed the trustees' high appreciation of the services thus given. Mr Addison responding for the board, spoke of changes in the type of patient and the severity of the disease seen at Alton. The hospital he had founded to deal with surgical tuberculosis which was then unprovided for otherwise the cases being crowded into children's hospitals under unsuitable conditions. Other institutions had since been started and surgical tuberculosis was now a disappearing disease unfamiliar to the younger medical generation. At Alton instead of a nine months waiting list they now had very few cases of tuberculosis waiting to come in, and they had therefore enlarged the scope of the hospital so that they were prepared to take almost any kind of disease. Sir Henry Gauvain who proposed the health of the City Corporation disclaimed credit for the hospital but said his life there had been very happy. Sir Charles Batho responding said that the City had never dispensed money to better purpose than to Alton. Sir Charles Gordon Watson proposing The Worshipful Company of Barbours gave his reasons for thinking that their picture of Henry VIII presenting the charter though true, think it is by Holbein is really only a copy of the one belonging to the Royal College of Surgeons in England. But Mr Maurice Hovenden the master refused to be drawn into the controversy and contented himself and his hearers by showing some of the company's other treasures.

Those present included Sir Frederick Mervin, Mr F. H. Treloar and Mr T. J. Harrowing (treasurers), Mr D. H. G. Holborow (master) and the following members of the medical

board or consulting staff: Mr Adkin, Mr P. Maynard, Mr R. S. Brew, Dr Reginald Lightwood, Mr L. A. Lindsay, Dr L. S. T. Burrell, Dr J. T. Hunt, Mr T. Pomfret, Mr R. Charles Gordon Watson, Prof. E. W. Hey Groves, Dr J. H. Thurnfield, Mr A. Simpson-Smith, Dr F. H. Young, Mr N. A. Jory, Mr J. H. Doggart, Dr R. A. Lyster and Mr R. L. Vollum D.Phil.

Birmingham Hay fever Clinic

At the annual meeting of the Birmingham Ear and Throat Hospital it was announced that a clinic has been established there this year where treatment will be available for those who suffer from hay fever.

Birmingham United Hospital

This hospital (formerly the General Hospital and the Queen's Hospital) during last year treated 121,303 patients. There was a small surplus on the year's workings, and an increase of nearly £6000 in ordinary income. The contributory association gave £70,925 an advance of £3000 on the previous year.

Tuberculosis in Sweden

The Swedish National Anti-Tuberculosis Association is arranging an inquiry into the incidence of tuberculosis in various trades and occupations especially among workers aged 18-25. An inquiry carried out by students on their own initiative showed that at least 2 per cent were infected, most of them having no knowledge of the fact. Since then typographers, tobacco-workers, and bus employees have been investigated and are said to have proved surprisingly free from the disease. According to the Swedish International Press Bureau a study of 14,000 children going on in the Norrland provinces shows that in those regions of the far north the death-rate from tuberculosis is three times as great as in more southern provinces. Recently however the number of fatal cases has considerably dropped.

Golden Jubilee of St John Ambulance Brigade

The St John Ambulance Brigade will celebrate its jubilee after the coronation beginning with a reception at St John's Gate on May 14th. It was formed in 1887 and by its connexion with the Order of St John of Jerusalem is part of the oldest order of chivalry in the world, having its commencement in the eleventh century. The strength is now 101,917 (men, women, and cadets) in this country and overseas. As commandant-in-chief of the nursing corps and divisions the Queen will take part in the jubilee celebrations by reviewing the Brigade in Hyde Park on May 22nd. Other arrangements include a garden party at St James's Palace on May 18th given by the Duke of Connaught as grand prior of the Order, a service at St Paul's on the 23rd, and an investiture at Buckingham Palace on the 26th.

Tuberculosis Association

The annual provincial meeting of this association will be held at the Central Library, Manchester, on June 10th, 11th, and 12th under the presidency of Dr S. Roodhouse Glove. The first session will begin at 2.15 p.m. on June 10th when Dr Geoffrey Marshall and Mr H. Morrison Davie will read a paper on how long collapse therapy should be delayed. Mr J. E. H. Roberts will also speak on bronchiectasis in pulmonary tuberculosis and Dr O. M. Mustal (Montana) on pleural effusions after thoracoplasty. On the following morning the first paper will be given by Dr P. J. L. de Bloeme (Laren, Holland) on the treatment of unilateral pulmonary tuberculosis. Afterwards there will be a symposium on difficulties in dealing with the tuberculous problem at which Prof. A. Ramsbottom will speak as a consulting physician. Dr W. F. Jackson as a general practitioner, Dr A. Dove Cornac as medical superintendent of a mental hospital, Dr R. I. Lane as medical officer to a large factory, and Dr D. I. Sutherland as a tuberculous officer. In the afternoon a visit will be paid to the Manchester Sanatorium at Baguley. At the last session Dr J. B. McDouall will read a paper on the roentgenograph and Dr C. S. Anagnostis a paper on artificial pneumothorax in children. Problem cases will be presented by Dr L. H. A. Lask and Dr G. Jewell. In the afternoon a visit will be paid to other sanatoriums in the neighbourhood. Further information may be had from the hon. secretary of the association, Marston House, 26 Portland place, London W. 1.

Vacancies

Births, Marriages, and Deaths

BIRTHS

NICOLSON—On April 13th at Portsmouth the wife of Surg Lt-Comdr J H Nicolson R.N. of a son
NORMAN—On April 23rd, at Eton, the wife of Dr H Bathurst Norman of a son
PICKEN—On April 27th, the wife of Dr C B Picken Basset Southamton of a daughter

MARRIAGES

COLTART-ASKEW—On April 24th at the Church of St Bartholomew the Great E C William Derrick Coltart F.R.C.S. Eng to Margaret Askew
FORSYTH-RULAND—On April 16th at St Mary's River Labrador Charles Hogarth Forsyth, M.R.C.S. Eng. International Grenfell Association Service, to Clayre Louise Ruland
TEAR-GRACEY—On April 24th at Burrington Dore, Robert Donald Tear M.R.C.S. Eng., of Ramsey, Isle of Man to Kathleen Agnes youngest daughter of Lt-Col and Mrs T Gracey

DEATHS

DILLON—On April 27th, at Oxford Luke Gerald Dillon O.B.E. M.D. R.U.I. of Bodicote Oxon in his 76th year
LE PELLEY—On April 30th at West Bridgford Notts Amelia Maitland le Pelley M.B. Lond
PARKER—On April 26th at Clifton Bristol George Parker M.D. Camb, LL.D.
SARRA—On April 30th in London William Henry Sarra M.R.C.S. Eng. of Leigh-on-Sea Essex
V.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births Marriages and Deaths

GIFT OF MATERNITY HOSPITAL—A maternity hospital is being given by Mrs Fife-Jameson to the county of Angus It is estimated it will cost £7000

NOTES, COMMENTS, AND ABSTRACTS

THE MEDICAL HISTORY OF WILLIAM THE CONQUEROR

BY R R JAMES

As a general rule it is an unprofitable venture to speculate on the pathology of a hypothetical case such as that of the last illness of the Conqueror. But William's death offers food for reflection and may even be of interest to such minds as suffer from a taste for general information not promptly checked of which type the classical example is Mr. Joseph Painsbury.

Everyone knows that the Conqueror died as the result of an abdominal injury received during the sack of Mantes in 1087. At this time he was about sixty years of age. Of exceptional strength he had been a warrior from his youth upwards, even from the moment of his birth his strength was apparent, for when he was laid on the floor after delivery the gossips noticed how he grasped the rushes in his little fists. His life gave ample opportunities for receiving hard knocks.

Before discussing his last illness I should like to draw attention to two serious illnesses of which we have records. The first of these occurred most probably in the year 1002. It is not mentioned by any of the chroniclers and we only know of it from a charter in the cartulary of the cathedral church of St. Mary Coutances. A transcript of this deed is given by Round in his *Calendar of Documents in France*, of which great series it is No. 957. It is undated and is a recital of a charter of William, Duke of the Normans to the Church of St. Mary. William, while living, ill at Cherbourg, vowed that he would establish three Canons in the church if God and St. Mary would miss him from his sickness when his life was wholly despaired of and he was laid on the ground as at the point of death and gave the Canons of that church the relics of the Saints which he carried (about) in his own chapel.

One can only suppose, in view of William's after-history, that this must have been some acute infection, but I would not like to offer a diagnosis. Laying a patient on the ground when at death's door would not seem to be the best treatment for such conditions as enteric or pneumonia, but whatever was the matter the crisis of the illness seems to have coincided with the patient being turned out of bed on to the floor. William's second illness occurred in the year of the Conquest. After Hastings the Conqueror had made his base secure by occupying Dover the castle of which according to William of Poitiers he had made into a hospital for invalid soldiers the army having been seriously infected by dysentery. He then marched towards London along the Roman road, but when at Canterbury, or thereby, he was seized by violent illness which kept him out of action for a month. I imagine that this illness may have been an acute gastro-intestinal infection.

In spite of these illnesses William must have made a complete recovery as is instanced by his long march to Exeter early in 1088 by his harrying of the North in the following year and by that ghastly march across the Fenlands from York to Chester in the mid-winter of 1089-90. Coming now to the last year of his life we know that William had become exceedingly corpulent. He was resting at Rouen when some kind friend repeated to him the jest of the King of France. This was to the effect that William was lying in like a woman just delivered from travail. William came out with more than his usual calm for he swore that by the resurrection and splendour of God when I go to Ma^{ns} after my confinement I will light him up a hundred thousand candles. And about the middle of August before August 16th according to Florence of Worcester he invaded French territory and sacked Mantes.

It should be remembered that most of the English chroniclers were writing at a date later than that of 1087. Even that old gossip Orderic, who was more or less contemporary with the event does not say anything about any abdominal injury. I suspect that the authority for the statement is William of Poitiers but his works are not accessible to me. Roger of Wendover and William of Malmesbury¹ the former probably copying the latter both mention the fact that the Conqueror received an injury while his horse was leaping a ditch. But most of the other chroniclers merely allude to the heat of the flames and the unequal temperature while Roger of Howden states that on his return from Mantes William was attacked by dreadful pains in the intestines from which he grew weaker every day.² William of Malmesbury states that the physicians at Rouen³ on examining the urine predicted certain death. The Conqueror did not die till the morning of Sept. 9th so that at least a month intervened between the injury and death.

If one examines a reproduction of the Bayeux tapestry one gets some idea of the type of saddle of the period. It had a high pommel in front and apparently behind also. In one picture it looks as if the pommel reached nearly up to the level of the umbilicus in front and well into the lumbar region behind. William of course would have been clad in mail at the time. He was conscious and able to speak until the end. What lesion could have been produced in such a case? I think we may rule out any perforation of a hollow viscus. Was the extreme pain renal or biliary colic? Was there blood in the urine which made the physicians so sure of death? No one can say for certain, but I do not think the case can have been one of intestinal obstruction from such a condition as strangulated hernia. The possibility of injury to the perineum, bladder, or urethra has to be considered as well as an umbilical hernia, but I should like to suggest biliary or renal colic.

The last scene is in the Abbey of Caen. When they came to put William in his coffin the monks anticipating the lament of Mr. Soverbury that a few inches over one's calculations make a great hole in one's profits had made the stone coffin too small. In the attempt to force the body into the abdomen burst and a horrible stench filled the whole church. In writing this paper I have consulted Freeman's *Norman Conquest* and the *Life of the Conqueror* by Prof. Stenton as well as the chroniclers mentioned.

MEDICAL EVIDENCE AT LONDON OMNIBUS INQUIRY

On May 3rd at the first meeting of the court of inquiry appointed by the Minister of Labour to investigate and report on the issues of the London omnibus strike Mr. Bevin in presenting the case for the men called attention to the uncertainty of meal reliefs and said that the physical reactions of the men were such that they made the men different from those found in other industries, different in the sense that the reactions produced a psychology all its own. He added that there had been a suggestion that carbon monoxide was the principal cause of the trouble and the union had succeeded in getting the problem referred to the Industrial Health Research Board where it had been now for a couple of years. Dr. James Woodall, chief medical officer at Manor House Hospital, said that from his work there he had

the impression that there was an altogether undue incidence of gastric illness among both drivers and conductors, but admitted that he had not had time to analyse the hospital records. Dr H B W Morgan, medical officer to the Trades Union Congress, said he had also been struck by the number of men in transport work who complained of gastric symptoms.

At the second meeting of the court on May 4th Prof Millais Culpin, M D, who was called by Mr Bevin, said that he had made a study of occupational circumstances and physical types of patients with organic diseases of the stomach. Three years ago he took the opportunity of examining a number of bus drivers at the Manor House Hospital diagnosed as suffering from gastric conditions. He saw 17 cases himself and 14 were examined by an assistant—primarily to ascertain the extent of nervous symptoms. The interviews lasted from 30 to 40 minutes, the men being allowed to talk freely. He found that in some cases the nervous symptoms were really the ones that mattered. He did not always agree with the hospital diagnosis. Of the 31 cases there were 4 whose nervous symptoms were severe enough to call for treatment, some of them being, in his opinion, unfit to drive. From 8 men he elicited no nervous symptoms, but added a note implying his opinion that the men were of stable type but might break down. In reply to the chairman, Dr Culpin said that 17 of the men complained spontaneously about speed, 10 of inspection, 9 about fumes, 7 about vibration, and 5 complained of being afraid of the company's medical officer.

In reply to a question from Mr Bevin, Dr Culpin said that this preliminary examination had led him to the view that there was at least a strong *prima facie* case for a very thorough investigation into the effect of all these things on the men.

The court consists of Mr John Forster (chairman), Sir Arthur Pugh, and Mr Basil Sanderson.

DANGEROUS DRUGS REGULATIONS

WE have received from the Home Office copies of draft regulations which it is proposed to make under Sections 3 and 7 of the Dangerous Drugs Act, 1920. The proposed new regulations under Section 3 which relates to raw opium, coca leaves, and Indian hemp, will make no change in the existing law and are solely for the purpose of consolidating the rules in force by which the distribution of the substance named is controlled and restricted. The main purpose of the proposed new regulations under Section 7 of the Act is to make substantive the provisional rules which were made a year ago with the object of bringing the regulations of 1928 into conformity with the Poisons and Pharmacy Act, 1933, but it is also proposed to make certain other amendments. We will refer only to those which have a bearing on the prescribing of dangerous drugs. In Regulation 8 a slight alteration is made so that the provision exempting prescribers of medicines under the National Health Insurance Acts from fulfilling certain obligations shall be extended to prescriptions given in connexion with the health services of local authorities.

THE MEANING OF "TWO OR THREE TIMES"

Amendments are being made in paragraphs 2 and 3 of Regulation 9 for the purpose of resolving doubts which have arisen as to the meaning of "two or three times." The proposed new paragraphs are as follows—

(2) If a prescription expressly states that it may subject to the lapse of a specified interval or of specified intervals, be dispensed a second or third time, the drug or preparation thereby prescribed may, as the case may be, be supplied a second or a third time after the specified interval or intervals and no more, but, subject as aforesaid, a prescription shall not for the purposes of these regulations be taken to authorise the drug or preparation prescribed to be supplied more than once.

(3) The person dispensing a prescription shall, at the time of dispensing it, mark thereon the date on which it is dispensed, and in the case of a prescription which may be dispensed a second or third time, the date of each occasion on which it is dispensed, and shall, unless it is a health prescription, retain it and keep it on the premises where it is dispensed and so as to be at all times available for inspection.

Alterations proposed in Regulation 11 are the insertion of the common names (eucodal) for dihydrohydroxycodone, (dicodid) for dihydrocodone, and (dilaudid) for dihydromorphine.

AN AMENDMENT AND A REDRAFTING

Regulation 14 is being amended in order to make it clear that signed orders for dangerous drugs must be preserved for a period of two years in the same way as other documents relating to such drugs.

Regulation 16, as redrafted, is as follows—

Nothing in these Regulations shall apply to—

(a) any of the drugs or preparations mentioned in the fourth schedule (see below) to these regulations or to a drug or preparation which has been denatured in manner approved by the Secretary of State,

(b) (i) any prescription issued for the purposes of a scheme for testing the quality and amount of the drugs and appliances supplied to insured persons under the National Health Insurance Acts, 1924-1935, and the regulations made thereunder, (ii) any prescription issued to a sampling officer for the purposes of the Food and Drugs (Adulteration) Act, 1928.

THE FOURTH SCHEDULE

The amendment to the Fourth Schedule is one of the most important being made in these regulations. In order to bring English legislation into line with the International Conventions with regard to "exempted preparations," a Declaration by His Majesty in Council is being made with effect from July 1st, exempting from the Acts (and consequently the regulations) all the preparations which have been exempted from the International Opium Convention, 1926, on the recommendation of the Health Committee of the League of Nations. The effect of this Declaration in Council is that from July 1st the Dangerous Drugs Acts will not apply to the preparations named in the Schedule to the Declaration, and therefore export licences will not be required for the export of such preparations. The Fourth Schedule is as follows—

Pulv. Cretæ Aromat. c. Opio, B.P. 1932.

Cocaine Eyedrops—a preparation consisting of an admixture of cocaine in castor oil with mercuric chloride in a proportion of not more than one part in 200 of cocaine and not less than one part in 3000 of mercuric chloride.

Methylmorphine and ethylmorphine and their respective salts and any preparation, admixture or other substance containing any proportion of methylmorphine or ethylmorphine associated with an inert substance whether solid or liquid, and preparations and admixtures or other substances containing more than 2.5 per cent of methylmorphine or ethylmorphine (calculated as pure drug) associated with other medicinal substances.

Methylmorphine and ethylmorphine will be exempted from these regulations because they are subject to a separate code of regulations which remains unaltered. Certain preparations of these drugs are also included in this Schedule because as the result of an Order in Council, Part III of the Dangerous Drugs Act, 1920, is being applied to them as from May 1st, but they are not being brought under these regulations which deal only with the home trade. A further amendment to this Schedule is the insertion of cocaine eyedrops. The effect of this amendment is to remove this preparation from control by the regulations. In consequence, factory owners and others will be free to purchase this preparation and the authorities granted in 1921 to these persons will be revoked as from the date on

which these regulations come into operation *Pule Creta Aromat c. Opio* will continue to be exempt from the regulations. Licences will be required, however for the export of drugs in this schedule from the United Kingdom

PRESERVATION OF MENTAL HEALTH

FOR the prevention or avoidance of a mental break-down Dr O C Easterbrook recommends that the person with a nervous predisposition should clearly recognise his weakness and that others with whom he comes into important contact should recognise it as well (*Med Offr* April 17th p 181). The personal or direct evidence of instability will include a previous history of any psychosis or neurosis or of morbid tendencies faulty habits and vices; some congenital or nervous defect a neurotic or degenerate physiognomy or physique or an abnormal reaction to the ordinary experiences of life. The great consolation which he sees for the person with a nervous constitution is that the neurotic is the potential pioneer neurosis and psychosis are weeds, indicating a fertile soil which will produce genius and inventive ability. If the neurotic would avoid a break-down says Dr Easterbrook he must lead a quieter life and take greater care of his health than his more stable brother. There are of course types of neurosis which have as their principal expression a pampering of the body or mind and a shrinking from stress and responsibility and Dr Easterbrook would probably admit that for patients like this it is more important to get outside themselves and experience the rough-and-tumble of life. There are many psychoses, minor as well as major, which cannot be avoided by any amount of care or self knowledge; illnesses which in fact forbid self knowledge by their very nature.

REGALCITRANCE AT MEAL-TIMES

AMONG journals of practical puericulture the monthly magazine called *Parents* now in its fourth volume, has won itself a good place. Those who have children on their minds will nearly always find something enlightening in its pages and the contributions are apt to be both sane and interesting. Contributors to the March issue include Dr Victoria Bennett Dr Winifred de Kok, Dr A Morris Johns Dr L Appell and Dr Lindsey Batten. Dr Batten's article entitled *Do you dread meal-times?* is concerned with the child who does not respond to the suitable food provided for him and his advice deserves wider circulation. He begins by pointing out that food requirements vary enormously and that the parent must not insist too much on convention—some children seem to have a natural preference for the continental breakfast. The real question is whether the child thrives on what he takes. If he is actually eating too little for his health and if his small appetite is a cause rather than a symptom it will be necessary to look into his motives for refusing food. The self-assertive instinct—the desire for fame, notoriety or power—causes most of the trouble and Dr Batten's rule is that it is always wrong to comment on a child's behaviour in his presence. We should treat him in this respect exactly as we treat a respected friend or guest. We do not comment in his presence on our guest's small appetite or his habit of not eating fat; it would offend him and it will either offend our child or it will make him feel important and encourage him to do it again. There is very little to choose between praise and blame. All comment is bad. A warning is also given against conflicts and it is here that the adult should exercise his far seeing sagacity. Is it to be a row about pudding? Off no pudding at all. Who knows but by tea-time it may be regarded as a treat. Is it some particular article of diet? Banish it from the child's plate or even from the table for some weeks and try again. As for discipline Dr Batten holds it perfectly reasonable to make and enforce a rule that

a child who refuses his meat course shall have no pudding or that he shall finish what he has asked for; but orders must be reasonable polite and unemotional the mother ought to have a shrewd idea that they are likely to be obeyed without a fuss and (once more) there must be no comments at all. The child must be induced to believe that whether he eats or leaves his dinner is a matter of indifference to everyone present but at the same time everyone does as a matter of fact eat their dinners and he will do the same.

Parents of younger children may get more immediate profit from an article on *Peaceful Bedtimes* by Mary Chadwick, S.R.N., which appears in the May issue of the same journal.

THE LURE OF LONDON

IN his third report on the special areas the commissioner Mr Malcolm Stewart drew attention to the recent immense growth of the outer ring of London the population of which in the twelve years 1921-33 increased by 1,000,222 as compared with an increase of 1,307,078 in the rest of England and Wales. This increase was due mainly to migration from inner London and from the provinces. The reduction of the congestion of inner London is of course, wholly desirable. Migration from the provinces depends largely on the fact that London the best market in Europe provides an irresistible attraction to new ventures. To the Londoner this concentration of population brings with it increasing difficulties, expense, and loss of time in the transport of himself and his goods and makes him increasingly vulnerable to attack. To the rest of England and Wales this removal of a largely young adult population to London and the setting up of most new industries in that area is a serious matter and is well exemplified by the returns of the Port of London which has increased its share of the foreign trade of England and Wales from 15 per cent in 1913 to 20 per cent in 1935 while the west coast ports have shown a fall of 11 per cent in the same period.

We see then that the lure of London, the favourite theme of the Victorian novelette is a very real thing at the present day and that the streets paved with gold legend persists in a practical form.

Metropolitan Man—Mr Robert Sinclair sets himself to demolish this legend and to show that every institution and habit of life that the Londoner holds dear is muddled inefficient or undesirable. His business, his leisure, his severals, his public health organisation, education, town planning and transport are discussed in turn and the general impression conveyed is one of unmitigated gloom. The most casual reader is soon driven to remark that things really cannot be as bad as all that. Mr Sinclair's method of producing his effect is firstly to omit any evidence which may show a satisfactory or improving state of affairs and secondly to warp or to state his statistics in such a way as to give an alarming and often misleading impression to the mind of the reader. He omits or explains away such things as the care of the pre-school child at infant welfare centres, the steady fall in infant mortality and tuberculosis and by confusing nutrition with nourishment arrives at the startling result that one in six of London's children is under-nourished. By further arithmetical gymnastics he shows that the children in schools found to be verminous amounted to 14 per cent when the true figure was 3 per cent. When his figures are correct the lay mind may still be led astray. One may quote: 50 per cent of children and 87 per cent of adults are infected with tuberculosis. One in three of Londoners dies in the workhouse. For every minor chance of being killed in a min the Londoner has six chances of injury in the street. He adds to the horror by referring to the pits as a hazard, liable to errors of refraction as blind as and

¹ *Metropolitan Man* by Mr Robert Sinclair, London, A.C.U. and Unwin 1937. 3s. 3d. 11s. 6d.

to minor ailments as disease, and he comes to the conclusion that "the greatest metropolis of the twentieth century is dirty, poor, unorganised, factious, ignorant, aimless, and leaderless" If this does not deter Mr Malcolm Stewart's migrating thousands, nothing will

INACTIVITY IN THE TREATMENT OF PUERPERAL FEVER

THE essence of the "absolute abstinence" method of treating puerperal fever, according to an exponent, J B González, is to refrain from all local examination or treatment, trusting to the patient's own resistance to overcome the infection. The medical attendant must be content, therefore, with a presumptive diagnosis and must be prepared to persist in his course of masterly inactivity even when the patient's condition appears to be growing worse. Writing in the *Semana Médica* for March 4th González says that, since 1919, he has treated all cases of puerperal fever in the maternity department of the hospital at Durand in this way, with results which he describes as excellent. He gives no figures, however, and while he must have credit for early condemnation of unnecessary interference, it is, unfortunately, impossible to believe that the patients' own resources, if left entirely to themselves, can generally be relied upon to reduce the mortality, as in his experience, almost to nil.

THE DIRECTOR OF RESEARCH

THE *Deutsche Medizinische Wochenschrift* for March 19th devotes several pages to a discussion of mentalities and tendencies in such centres of learning as Heidelberg, Würzburg, and Jena. Writing from the Würzburg Medical and Neurological Hospital, E Grafe asks "Are the collaborators of the heads of hospitals and institutes to work as an orchestra with a definite programme and playing previously chosen music under the baton of a conductor? Are we to train members of an orchestra or soloists and prospective conductors?" In support of the latter alternative, reference is made to two great German physiologists living at the end of the last century. Carl Ludwig and Eduard Pfüger may rank as equals as far as their own contributions to science are concerned, but their influence on their surroundings was as dissimilar as possible. Pfüger had need only for assistants willing to work on the lines he laid down, and he parted with them as soon as he caught them straying. The result of this policy was that he founded no great school. Ludwig, on the other hand, filled many a chair of learning throughout the world with his pupils, some of whom followed disciplines quite different from his own. He was satisfied with merely stimulating his pupils to stimulate themselves, and he left it to them to follow their own bent. He believed in developing the individuality and gifts of his pupils in as congenial a scientific atmosphere as possible. It is pleasant to-day to see this contrast drawn by a German who leaves no doubt that it is Ludwig's method that has his sympathies.

THE COLORIMETRIC DETERMINATION OF OXIDATION-REDUCTION BALANCE—A communication from the B D H Analytical Laboratories. Second edition, revised. Published by The British Drug Houses Ltd., Graham-street, London, N 1. Pp 19. A compact introduction to the theory and practice of the use of indicators to determine oxidation-reduction potentials is provided by this little book. It describes simply the nature of electrode potentials, gives the oxidation-reduction curves of some of the more usual indicators, and briefly indicates for what purposes these indicators may be employed. Practical methods such as the testing of sewage effluents, the testing of milk by the methylene-blue test, and the recent applications of the indophenol indicators to assay of vitamin C are mentioned. A brief guide to a few of the numerous publications on this subject is included. The book is free to medical men.

Appointments

ABERNETHY, CHRISTINE, M B Glasg, D P H D M R. Radiological Officer at Ancoats Hospital Manchester.
ALLEN, J S, M B Belt, D P M. Second Assistant Medical Officer at the Manor, Epsom (L.C.C.).
BELL, G J, M B Lond, D P M. Second Assistant Medical Officer at Park Prewett Mental Hospital Basingstoke.
DUCKWORTH, G, M R C P Lond, Hon Dermatologist to St John's Hospital, Lewisham.
LISNET, A A, M B Duhl, D P H. Deputy Medical Officer of Health and Deputy School Medical Officer for Leicestershire.

THURSDAY—10 A.M. neurological and gynaecological clinics. Noon fracture clinic. 2 P.M., operations, medical, surgical, genito urinary, and eye clinics.
FRIDAY—10 A.M. medical wards, skin clinic. Noon lecture on treatment. 2 P.M. operations medical, surgical, and throat clinics.
SATURDAY—10 A.M. children's and surgical clinics. 11 A.M. medical wards.
The lectures at 4.15 P.M. are open to all medical practitioners without fee.
MANCHESTER ROYAL INFIRMARY.
TUESDAY, May 11th—4.15 P.M., Mr W. R. Douglas. Lesions of the Common Bile-duct.
FRIDAY—4.15 P.M. Mr D. V. Sutherland. Demonstration of Surgical Cases.

ADDRESSES AND ORIGINAL ARTICLES

OBSERVATIONS ON
MALIGNANT DISEASE OF THE
THYROID GLAND*BY ALFRED HAAS M.D.
OF MUNICH

THE proper study of human life to paraphrase Pope is the study of human relationships. When human beings either as a community or as individuals fail to develop and maintain adequate reciprocal relationships neurosis makes its appearance as may be observed in current European history or amongst the visitors to any medical consulting room! When the cells of which the human organism is composed default in the same way there is engendered disease—inflammation degeneration neoplasm—as may be seen in any operating theatre or post mortem room.

In no cell community is this better illustrated than in the thyroid gland which has to bear a large share of the stresses that the human frame is called upon to endure psychological and chemical. There is no need then for surprise that the thyroid gland reacts in many curious ways some of which it is my purpose to describe here. The results of its failure to function or of its over activity are familiar to all but it is not quite so well known what happens when hypertrophic and degenerative changes pass over the narrow borderline between degeneration and malignancy. It is this aspect which forms the burden of this communication.

There is general agreement that in mountainous countries where goitre is endemic carcinoma of the thyroid is relatively common because it always develops in a gland already the subject of degenerative changes very often the so-called adenomatous or nodular goitre.

Estimates of the frequency of this malignant change vary with different observers, but the following

FIG 1a.—Metastasis of a papillary adenocarcinoma of the thyroid with very large alveoli. The stroma is very rich in fibroblasts.

short statistical summary gives a general idea of its frequency. Of 3,000 cases published by Kocher 2% were proved malignant and 7% were doubtful (0.8 to 8.8 per cent). Wilson investigated 10,682 goitres and among these 207 were malignant (2.78 per cent). I myself observed that among 5,000 goitres operated upon between 1870 and 1930 2% of them were cer-

tainly malignant that is to say 1 in 143 (0.7 per cent). Among these every kind of malignant change was fairly evenly represented. Only true sarcomas were rare (2).

Speaking generally malignant thyroid tumours are rare. The New York State Institute for Cancer

FIG 1b.—The small primary tumour of the thyroid. The picture shows the typical buds of the papillary cancer.

Research reports that in twenty four years there have only been 42 cases that is 0.37 per cent of all malignant tumours.

Carcinoma of the thyroid has one important characteristic which distinguishes it from carcinoma elsewhere. It relatively seldom gives rise to metastases in the lymphatic system but frequently the large thin walled veins on the surface of the goitre are invaded and dissemination takes place by the blood stream.

According to Bartels the lymphatics of the thyroid are arranged in two groups. One runs upwards medially and laterally following the perivascular lymphatic channels and secondary deposits may be found in the corresponding lymphatic glands. The second group runs downwards anterior and lateral to the trachea, and finally drains into the deep cervical and supraclavicular glands and this latter is the commonest site for secondary lymphatic deposit.

As I have said before invasion of the veins is the most frequent path of dissemination and the bones are the most frequent sites for metastases. Osseous secondary tumours are as common as in carcinoma of the prostate. The bones are involved in the following order of frequency: skull spine sternum humerus femur ribs pelvis clavicles jaw radius calcaneum. Visceral metastases are well known to occur often in the lungs sometimes in the liver and are not at all uncommon in the brain.

Another well known and important characteristic of thyroid tumours is that the primary tumour may be very small so small that apart from a histological examination it may not be found, yet the secondary deposits may be large and widespread. It is of interest that bronchial carcinoma sometimes behaves in the same way.

Last year I operated on a patient who had a nodule of the left frontal bone the size of half a crown. It was removed with a large piece of surrounding healthy bone and of the underlying dura which was involved. When I looked at the section it was that of a papillary carcinoma which I thought considerable. Its histological appearance

had its origin in the thyroid gland. As a logical sequel, ten days later I removed a fair-sized nodular goitre from the patient's neck. This was cut in serial sections, and after the most laborious examination of each piece the primary tumour was found, hardly larger than a pea (its histology corresponded exactly with that of the tumours in the skull). Figs 1a and 1b show these two tumours.

On the whole the best classification of epithelial

FIG 2a—Metastasis of a malignant adenoma of the thyroid. The metastasis shows only more adenomatous parts rich in cells with compression of the acini and also many alveoli and production of colloid on other parts.

tumours of the thyroid is that of Wegelin, which is based on that of Langhans

- (1) *Metastasizing malignant adenoma*—(a) The small cell adenoma (b) The large-cell adenoma
- (2) *The proliferating goitre of Langhans*
- (3) *The papillary epithelial tumours*
- (4) *The true thyroid cancers*—(a) Carcinoma solidum
- (b) the sarcoma form, (1) the medullary form, and (2) the cylindrical-cell carcinoma
- (c) Squamous-cell epithelioma

Formerly all these malignant tumours were grouped together on account of their sinister reputation, and even to day this view is held by many surgeons. It has been shown recently however by de Quervain and others that with a combination of operation and deep X ray therapy some remarkable results can be obtained in epithelial tumours.

METASTASIS IN BONE

There is one type of malignant goitre which does not easily go into this general classification, and it is of great interest to surgical pathologists. In the last few years I have seen two patients each with large bone tumours, which on section gave the histological picture of a nodular goitre. When the goitre was removed only adenomatous changes were found, and nothing to suggest malignancy. This is, of course, not an original observation. Cohnheim in 1876 published an autopsy case and thereafter quite a number of further cases were recorded, though in many of them a really adequate examination of the thyroid gland was not made.

In dealing with these cases most surgeons content themselves with either removing the metastatic tumour or irradiating it without removing the thyroid. This attitude, which may have been justified in some metastatic tumours, should now be modified because it is certainly possible by the combination of operation and radiation to considerably prolong the lives of these patients. As an illustration of this, a short account of the two patients just mentioned is appended.

A woman aged 61, was admitted to my clinic on 4th. 1933. Her story, which extended over ten

years, was as follows. She complained of slowly right-sided headaches accompanied by giddiness, frequent vomiting. Later a tumour developed in the parietal bone which steadily increased in size, became increasingly nervous and was troubled audibly bruit in the tumour; there was a medium-sized goitre to which she paid little attention because they are so common in Bavaria. Over the right parietal bone a fixed pulsating tumour the size of a tangerine, the skin over it was blue, and pulsation could be heard and felt. It was slightly diminished by compression of the artery. Pressure on the tumour produced no at its edge a distinct bony wall could be felt. There were no signs of intracranial pressure, cranial nerves were involved. The knee and ankle jerks were increased on left side.

In the neck was an ordinary rather hard goitre, lobe about the size of a fist, the left a little larger than right. There were no signs of malignancy or of adjacent structures. There was a slight increase in the pulse rate (102) and some cardiac dilatation. Radiography showed a circular defect of the left parietal

To sum up, here was an elderly woman with a very common type of goitre, who had a growing, pulsating tumour of the skull which caused a slight headache and giddiness. A secondary tumour was the most probable diagnosis. The patient's general condition was good, and so any particular risk she was operated on, using a local anæsthetic after a preliminary injection of Eucodal and scopolamine. When the tumour was exposed it looked just like an ordinary vascular goitre, and was removed together with a wide margin of normal bone and the underlying dura which was also involved. When the dura was partly raised the anterior aspect of the cerebral sulcus was also seen to be invaded and a thin layer of brain was resected with diathermy loop.

The patient recovered comparatively quickly. There was a post-operative paresis of the left arm and leg, but in a month this was so far recovered that she could use her left hand to perform simple movements. One month later a symmetrical goitre was almost completely removed, a very small amount of unchanged thyroid tissue being left on the right side. She recovered uneventfully from the goitre operation and was soon walking about the clinic.

FIG 2b—The goitre gives the same picture of small alveoli without definite lumina, and zones in which alveoli were more adult and contain masses of colloid.

training her partially paralysed arm and leg, and having intensive deep X ray therapy. Eleven weeks after the first operation she left the clinic and was able to do her ordinary housework.

Here then is a case interesting enough from a technical point of view, the sort of thing that any surgeon likes to do and report, but the major and real interest lies in the pathological examination of

these two tumours. The secondary skull tumour both grossly and histologically was just like an ordinary nodular goitre adenomatous areas without colloid alveolar areas containing colloid secretion. The thyroid itself was examined with great care but serial sections failed to show any signs of malignancy. Many parts exactly resembled the skull tumour.

FIG 3—Destruction of the ischium by metastasising malignant adenoma of the thyroid

The stroma showed marked and extensive hyaline degeneration and some of these degenerated areas were calcified (Figs 2a and 2b).

In June 1934 nine months later she returned complaining of pain in the back. There was tenderness of the fifth lumbar area; radiography however was negative. The pain was very severe and as it was presumably due to a metastasis she was given deep X-ray therapy. After three weeks of this the pain had gone. She came back again in March, 1936, nearly two years later with violent pain in the right lower limb, especially severe round the hip. This time a radiogram showed widespread destruction of the ischium and a secondary in the second lumbar vertebra (Fig 3). She was again given intensive irradiation and since then has been well and able to do her work.

This case illustrates the typical course of such a malignant adenoma showing its nature only by a very slowly developing secondary deposit in the skull, without signs of malignancy in the primary growth itself, and what was left behind of the thyroid showed no change in spite of the growth of further secondary deposits months later—and with it all, the patient can do her work.

I have had another similar case.

A man aged 41 came in September 1936 complaining of pain in the left leg for three years and subsequently his right leg became painful. For the last three years there had been a slowly growing painless tumour over the sternum and about a year previously a goitre had been removed in another hospital. During the war he was said to have had tuberculosis but had recovered.

On examination he was a strong man with no signs of disease except those I am about to describe. Over the manubrium sterni at the level of the left sternoclavicular joint there was a tumour the size of an apricot situated in and expanding the bone which pulsed and a systolic murmur was audible. In the upper lobe of the left lung there was dullness, and on auscultation sibilant and coarse rhonchi. There was tenderness on palpation over the third, fourth and fifth lumbar vertebrae; movement was limited and the muscles were rigid. Pressure on the head produced intense pain in the back. Both ankle jerks were absent and knee jerks diminished and there was hyperreflexia on the external a part of the dorsum of the foot (second sacral) and a perianal anaesthesia.

X-ray films of the lumbar spine showed a large area of bone destruction in the body of the fourth lumbar. It

will be seen that only a thin shell of bone remained (Fig 4).

This clinical picture is as you see very characteristic of malignant goitre: only the absence of recurrence in the neck was against it. I found out that it was a large adenomatous goitre which had compressed the trachea and on this account was removed. Microscopic examination was done by a distinguished pathologist Prof Oberndorfer now in Istanbul who found no sign of malignancy in many sections.

Fig 5 shows a section of such a goitre. Most of the acini are compressed so that the lumen is obliterated and many parts are without colloid; there is no penetration of the basement membrane and no invasion of the vessels. Further to elucidate this case a piece of tissue was removed with a diathermy loop. It was a vascular goitre like tumour and so on microscopic examination proved to be a colloid adenoma with colloid filled acini (Fig 6). The stroma showed hyaline degeneration and there was a thick strong capsule.

After intensive irradiation the chest tumour diminished rapidly; three weeks later it was below the level of the sternum. The symptoms of compression of the cauda equina were relieved by extension, but in order to prevent collapse of the vertebral body an Albee operation was done on Oct. 14th, 1936, a solid bone-graft from the tibia being used. Three weeks later the spinal metastasis was irradiated with the expected result that the pain disappeared. The reflex and sensory changes remained unaffected. Four weeks after the Albee operation he was walking with a light spinal brace and in six weeks he left the hospital.

This second case has some interesting points of difference from the first. The patient was a comparatively young man who four years ago had an ordinary nodular goitre removed but a year later began to have sciatia which despite treatment slowly increased until it was so obvious that his cord was compressed. Again one year after the pains began he had developed a tumour in the chest and this localisation suggested a primary thyroid growth which was confirmed by biopsy. Intensive irradiation and spinal fixation relieved the symptoms. I think that before long he will have a further recurrence not only on account of his youth but because the tumour seems very malignant.

FIG 4—Irreversible destruction of the body of the 4th lumbar vertebra by metastasising malignant adenoma of the thyroid

TWO TYPES OF MALIGNANT ADENOMA

Reference to the classification above shows that there are two types of malignant adenoma which are both extremely rare. These two cases just

described belong to the small cell type, the large-cell type is even rarer still. Under the microscope their appearance is surprisingly uniform. Langerhans, when he was describing them, said "When you have seen one field you have seen the lot", the cells are strikingly large and their protoplasm richly granular.

To look at they are very much like the suprarenal gland and have characteristic small alveoli, appearing as isolated knobs in the middle of the goitre. Getzow, who is the continental authority on the subject, believes that they arise from tissue rests of the branchial arch, which give rise to tumours having a syncytial character. Groups of cells having these characters, but without tumour-formation, are often found in the normal thyroid gland. This view is however disputed by other authorities.

When they grow they form a hard, isolated tumour either in a normal gland or in nodular thyroid. Later they become fixed and infiltrate widely so that they are often mistaken for an inflammatory condition. Their prognosis is relatively good because, if they are removed with the capsule, they are usually cured, especially if they are irradiated afterwards. I myself have not seen a case and reports of them are rare.

In this rare type and also in the ordinary malignant thyroid the onset of malignancy produces quite definite physical signs. The tumour increases in size and produces symptoms of pressure on the trachea and œsophagus, such as dyspnoea and dysphagia. The patient goes rapidly downhill as the tumour increases in size and fixity. Contrast this with the cases I first described, a perfectly ordinary adenoma with a long history, a solitary, equally slow growing tumour in a bone, the two apparently unconnected until someone explores the bone tumour and finds that histologically it is identical with a colloid goitre.

FIG 5—A picture of adenomatous and colloid goitre

If the surgeon is enterprising enough to remove the goitre, not a trace of malignancy is found. What explanation is there for this? If one considers the nodular goitre to be a true adenoma, it must be logically admitted that here we are dealing with a malignant adenoma. But if this view be entertained, it must not be confused with the precancerous conditions which we find in the breast and rectum, described in this country by Cheate and Dukes.

If these adenomata undergo malignant degeneration they themselves have the characteristics of a true carcinoma and their metastases are histologically malignant.

There is however another explanation advanced by Ribbert, who suggests that the entry of goitrous

FIG 6—The metastasis is the exact copy of the goitre

tissue into the veins is, so to speak, in the nature of an accident, it is the result of pressure atrophy and not true active infiltration. Hence the rarity of the condition. Graham, discussing thyroid malignancy, believes that invasion of the blood-vessels is the true criterion of malignancy.

Schworer has made an attempt to prove that trauma is mostly the cause of this invasion of the vascular system. He points out that many cases of metastasis appear after an operation for goitre. My second case would perhaps support this idea.

Dunhill has emphasised an important fact in connexion with malignant disease of the thyroid. He has shown that such changes only take place after a long period, much longer than in other types of carcinoma, often 30-40 years. In this type of "malignant adenoma" the history extends from 5-10 years—a marked contrast with the true carcinomata. The metastases often occasion curious mistakes in diagnosis, they may, by their pulsation, resemble an aortic aneurysm, and histological diagnosis may be difficult and inadequate on account of the hæmorrhage caused by excision of a small piece. This however is the only way in which the diagnosis can be made.

Finally I want to make another distinction between these malignant adenomata and true cancer of the thyroid, this concerns their prognosis and reaction to treatment. Von Eiselsberg, a master surgeon with an unrivalled experience, gives it as his opinion that in every case of malignant goitre the metastasis should be irradiated and the gland either removed and irradiated or if this is impossible simply irradiated. This, I think, represents the general opinion to day.

Now with true cancer of the thyroid cures are by no means uncommon. I myself in 1926 was able to show 11 cases free from recurrence after more than six years. In one of these a segment of the trachea had been removed, another patient who had a total thyroidectomy is alive and well eleven years later but has to take thyroid extract daily. But I do not

think you will find any cases of malignant adenoma which can really be called cured their lives can be prolonged and their comfort increased by operation and irradiation but they cannot be cured.

In sarcoma of the thyroid the course is still more rapid. Six to nine months is the limit and they are unaffected by either operation irradiation or a combination of these two so we must come to the reluctant conclusion that excluding sarcoma malignant adenoma is in spite of its initial response to treatment and its slow course in fact the most sinister of all thyroid tumours.

SULPHÆMOGLOBINÆMIA AND METHÆMOGLOBINÆMIA FOLLOWING ADMINISTRATION OF p AMINO BENZENESULPHONAMIDE

By J P J PATON M.B. Class

RESIDENT MEDICAL OFFICER, BELVIDERE ISOLATION
HOSPITAL, GLASGOW AND

JAMES C EATON B.Sc. M.B. Class A.I.C.

BIOCHEMIST AND ASSISTANT PHYSICIAN FOR METABOLIC DISEASES
THE VICTORIA INFIRMARY OF GLASGOW

A SEVERE toxic effect resulting from one of the p aminobenzenesulphonamide drugs (Protosil Album) recently came under the observation of one of us (J P J P).

It has been suggested that poisoning from this substance is associated with administration of sulphates (Colebrook and Kenny 1936 Diccombe 1937). Ten cases of cyanosis following administration of p aminobenzenesulphonamide (hereafter referred to as sulphanilamide for brevity) have been proved to be associated with sulphæmoglobinæmia (Colebrook and Kenny 3 Diccombe 6, Frost 1). Of these 8 received magnesium sulphate by mouth and 1 had a dressing of sodium sulphate. We have investigated this and 10 other cases treated with sulphanilamide with or without magnesium sulphate administration to determine whether sulphates are actually concerned in the toxic effects of these drugs. Of our cases 4 developed sulphæmoglobinæmia of which 3 had had sulphates before admission. Four patients who received no sulphates developed methæmoglobinæmia. This condition has not previously been recorded after sulphanilamide.

A CASE RECORD

The history of the original case is as follows.

CASE 1—Female aged 28. Gave birth to a child on Feb. 23rd 1937 after long rotation from an occipito posterior position and application of forceps. The puerperium was uneventful from then until March 15th when she developed pain in the left breast. From March 7th until admission she received 0.3 gramme protosil album every two hours apart from the night hours—i.e. 2.4 g. per diem total dosage 9.6 g.—and from March 8th till 11th inclusive she had 1 to 2 teaspoonfuls of magnesium sulphate in the morning. On the 8th the breast was incised and pus evacuated. A dressing was applied the nature of which is unknown but which may have contained magnesium sulphate.

The patient was admitted on March 11th as a case of puerperal pyrexia with an alarming degree of cyanosis and apparently moribund. The temperature was 99.8° F. the pulse rate 116 per minute and the respiration rate 22. Cyanosis was particularly conspicuous in the face lips and finger nails. Pulse volume was very poor. Cardiac dullness was slightly increased to right and left. Heart sound was pure but of poor quality. For two days after

admission there were some fine râles at the base of the right lung and the percussion note over this area was slightly impaired. There was slight tenderness in the lower abdomen. The urine was dark, contained a trace of albumin pus and B. coli, and reduced Fehling's solution. Rothera's test was positive. No hydrogen sulphide could be detected. There was a deposit of pink urates.

Treatment was begun at once with administration of oxygen through a Haldane's mask but without apparent effect on the cyanosis. A pint of saline and 5 per cent glucose was given intravenously at 4 P.M. on March 11th after which the cyanosis diminished and the pulse improved. By 3 A.M. on the 12th the cyanosis was again more obvious and the pulse poor. Half a pint of unusually dark blood was withdrawn from a vein and one pint of citrated blood transfused. This caused a definite diminution in the cyanosis. By 10 A.M. the patient's condition had much improved. Potassium citrate rectal saline and glucose were given freely and oxygen for 20 minutes every four hours. On examination of the urine Rothera's test was now negative but there was still a reduction of Fehling's solution. A sample of blood withdrawn from the median basilic vein had a peculiar dusky brown colour.

The administration of oxygen was continued as above until March 16th by which time the cyanosis was much less marked though still distinct. Cyanosis was still apparent clinically though in progressively diminishing degree until the 18th after which it was not possible to say with certainty that it was present. Smears from the breast showed *Staphylococcus aureus*. A cervical smear showed anaerobic streptococci. On March 11th transillumination of the lobe of the ear and spectroscopic examination showed a well marked band in the red part of the spectrum. A sample of venous blood was examined spectroscopically on this date and showed a very well marked spectrum of sulphæmoglobin. Spectroscopic examination of the blood was made daily until March 30th and then on alternate days until April 26th—i.e. until 40 days after stopping administration of protosil album—but the characteristic band of sulphæmoglobin in the red part of the spectrum was still faintly visible. The sulphæmoglobin was entirely intracorporeal. The patient made a perfect recovery.

The findings for the other cases are shown in the accompanying Table. All the patients were females in the puerperium except Case 13 (who was a child with streptococcal interlobar emphysema) and were diagnosed as puerperal fever or septic abortion. Cases 6 and 12 being complicated by bilateral mastitis and plegmæmia alba dolens respectively.

Sulphæmoglobinæmia associated with giving sulphur or its compounds has been noted after drugs other than sulphanilamide. Van den Bergh and Revers (1931) recorded sulphæmoglobinæmia in a patient following treatment with Iridium (phenylazo α^1 dlamino pyridine) and showed that this was associated with administration of sulphates. Hartup and Waterfield (1930) found sulphæmoglobinæmia after acetphenetidine (this is discussed more fully below). By means of *in vitro* experiments van den Bergh and Revers showed that pyridium accelerates formation of sulphæmoglobin by hydrogen sulphide. This property of catalysing sulphæmoglobin formation is apparently shared by a large variety of substances most of which are amino compounds or derivatives of amino compounds (van den Bergh and Weinga 1925). We have repeated and confirmed these *in vitro* experiments with pyridium and have made similar experiments with sulphanilamide. From our observations however no appreciable acceleration of the formation of sulphæmoglobin could be detected by the simple method used on the addition of sulphanilamide to the mixture of oxyhaemoglobin and hydrogen sulphide.

EXPERIMENTAL

Spectroscopic examination of the patient's blood was performed by means of a Leitz microspectroscope. The

SUMMARY OF THE FINDINGS

Case	Age	Dose of mag sulph (by mouth)	Dose of sulphanilamide reckoned from day of admission	Spectrum of blood	Remarks
GROUP 1					
2	26	5 ml during 5 days preceding admission	2nd day at 6 A.M., 6 g at 10 A.M., 6 g Total dose 12 g	2nd day at 1 P.M. SHb present Detectable till 23rd day	2nd day cyanosis marked Detectable till 20th day
3	27	3i daily for 4 days preceding admission	1st day 40 ml Pronto-soluble (Bayer) intramuscularly 2nd day 24 g sulphanilamide by mouth	3rd day SHb present Still detectable on 43rd day	3rd day cyanosis marked 50 ml. 1 per cent methylene blue intravenously failed to relieve cyanosis or sulphæmoglobinæmia Cyanosis detectable till 17th day
4	31	Nil	Variable 33rd-48th days Total 108 g in 16 days Average 6.75 g per day	Trace of SHb on 48th day Detectable till 66th day	48th day very slight cyanosis following dose of 24 g sulphanilamide on 46th day Marked secondary anemia
GROUP 2					
5-11		Nil	12 g daily for periods from 6 to 22 days Total dose 72 to 264 g	Normal	No cyanosis
12	20	3i just before admission	12 g daily 4th-25th days Total dose 264 g	"	"
13	3	Nil	3 g daily for 19 days	"	"
14	32	"	2nd day 12 g 3rd day 24 g 4th day nil 5th & 6th days 12 g each Total dose 60 g	"	4th day cyanosed Much diminished on 5th day Bronchitis
15	25	"	2nd-13th days 12 g daily Total 144 g	"	13th and 14th days slight cyanosis
16	31	3i daily for 3 days before admission	12 g daily 2nd-10th days Total 108 g	"	No cyanosis
GROUP 3					
17	42	Nil	1st day 8 g 2nd day 12 g 3rd day 36 g 4th day 24 g 5th day 6 g Total 86 g	6th day MHb present 6th day normal	6th day cyanosis marked, mental confusion 6th day slight cyanosis 4th day no cyanosis mentally normal 5 grains quinine hydrochloric t.i.d
18	30	"	2nd day 24 g 3rd day nil 4th day 24 g Total 48 g	7th day MHb present 8th day normal	3rd day cyanosed 4th day no cyanosis 5th-8th days slight cyanosis
19	30	"	1st day 4 g 6th-9th days 12 g daily Total 52 g	10th day MHb present 11th day normal	3rd day cyanosed 4th-8th days no cyanosis 9th day cyanosis marked Received hydrochloric acid
20	24	"	3rd day 12 g 4th day 8 g Total 20 g	4th day MHb present 5th day normal	4th day cyanosed 5th day no cyanosis Received hydrochloric acid

SHb = sulphæmoglobin

MHb = methæmoglobin

spectra were compared with that of a known solution of methæmoglobin in the comparison tube and the alpha band of the sulphæmoglobin shown to persist after addition of ammonium hydroxide, sodium cyanide, or ammonium sulphide to the blood (Wood Clark and Hurlley 1907, Harrop and Waterfield 1930). Blood from a finger prick was used, and was laked with a few millilitres of water. The alpha band was seen to lie between 6150 and 6280 Angström units and could be readily distinguished in position from that of methæmoglobin.

To determine whether sulphanilamide would accelerate sulphæmoglobin formation, 2 ml oxyhæmoglobin solution were placed in each of two test tubes. To one tube 5 drops of a solution of sulphanilamide in water, saturated at room temperature, were added and then a few drops of hydrogen sulphide solution to each of the tubes. One of the preparations was then placed on the microscope stage, the other being placed in the comparison tube of the spectroscop. In this way the spectra of the two samples could be watched simultaneously and the development of the spectra of sulphæmoglobin observed. The greater the quantity of H₂S added to the oxyhæmoglobin the more rapidly did the spectrum of sulphæmoglobin appear, but even using minimal quantities of H₂S sulphæmoglobin did not appear to be formed more rapidly in the sample containing sulphanilamide. The action of pyridium was observed similarly, adding a 0.25 per cent solution of this substance in water in place of sulphanilamide. In this case the spectrum of sulphæmoglobin appeared in a few seconds compared with several minutes for the sample without pyridium.

DISCUSSION

The 20 cases fall into three groups.

Group 1 comprises Cases 1 to 4. These patients all developed sulphæmoglobinæmia. In Cases 1 to 3 magnesium sulphate had been given, there was marked cyanosis (in Case 1 very extreme) and the spectrum of sulphæmoglobin in the blood was pronounced. In Case 4, where no sulphates were given, cyanosis was slight and the sulphæmoglobinæmia only just detectable.

Group 2 comprises Cases 5 to 16. In none of these was any abnormality found on spectroscopic examination of the blood and only in two (Cases 14 and 15) was any cyanosis seen. Of these 12 patients only 2 had received sulphates, and in one of these the administration of sulphates was stopped three days before giving sulphanilamide. Case 16 received sulphates until the day before giving sulphanilamide but failed to develop sulphæmoglobinæmia.

Group 3 comprises Cases 17 to 20. These patients became cyanosed though none had had sulphates. On examination of the blood it was found that methæmoglobin and not sulphæmoglobin was present. Comparing Groups 1 and 2, it is seen that while the patients in Group 2 received large doses of sulphanilamide for a long period without developing sulphæmoglobinæmia, those in Group 1 (Case 4

excepted) received much smaller total doses and rapidly developed sulphamoglobinæmia. This was particularly noticeable in Case 2 where only seven hours after giving the first dose of sulphanilamide the patient was markedly cyanosed and the blood contained sulphamoglobin. A possible explanation of the appearance of sulphamoglobin in Case 4 although no sulphates had been given is that intestinal stasis allowed reduction of other sulphur-containing substances in the bowel as is supposed to occur in enterogenous cyanosis and that these permitted sulphamoglobin formation in a similar fashion to exogenous sulphates. This is supported by the findings of Harrop and Waterfield mentioned below.

The formation of methamoglobin in Cases 17 to 20 was quite unexpected. As is well known drugs containing the sulphone group $-SO_2-$ such as Sulphonal and Trional produce methamoglobinæmia in susceptible persons and probably in anyone provided the dose is sufficiently great. Harrop and Waterfield (1930) have shown that while various aromatic organic compounds produce methamoglobinæmia if these substances are given along with sulphur the result is sulphamoglobinæmia. Apparently methamoglobinæmia is the true toxic result of a large dose of sulphanilamide or possibly of quite a moderate dose in an unusually susceptible person. Formation of sulphamoglobin takes place only when sulphur compounds are available as happens when they are present in the bowel in unusually large amounts.

We are unable to offer an explanation of the appearance of methamoglobinæmia in Group 3 where the dosage of sulphanilamide was, on the whole less than in Group 2. One of the patients had had quinine. Plasmoquine has been responsible for methamoglobinæmia but we are not aware of any such effect following administration of quinine despite its very wide use in the tropics. Nevertheless we have tried to eliminate this as a causative factor by giving Case 17 large doses of quinine without simultaneous administration of sulphanilamide. This did not result in a recurrence of the methamoglobinæmia. Two of the patients received hydrochloric acid for the purpose of aiding absorption (Foulls and Barr 1937). It may be that these patients received a greater effective dose. For the other cases, we are forced to that confession of ignorance—idiosyncrasy on the part of the patient.

The relative persistence of sulphamoglobinæmia and methamoglobinæmia is of some interest. While sulphamoglobin could be detected for more than six weeks after stopping administration of sulphanilamide methamoglobin could not be detected after 24 hours. This corresponded approximately with the cyanosis. When cyanosis was due to methamoglobin it disappeared very rapidly while that due to sulphamoglobin was much more persistent. These findings correspond with those of Waterfield (1928) in a patient in whom sulphamoglobin and methamoglobin were found alternately. Waterfield noticed that attacks of cyanosis associated with methamoglobin were transient the patient's colour rapidly becoming normal in the intervals with sulphamoglobin the cyanosis was persistent.

The persistence of sulphamoglobin is the more surprising on consideration of its mode of formation. Methamoglobin is the result of oxidation of the iron-containing part of haemoglobin but sulphamoglobin is believed to be an addition product. Carbon monoxide haemoglobin is also an addition compound of haemoglobin and is decomposed by oxygen so that in poisoning by carbon monoxide a few hours suffices

to remove it from the blood (Sollmann's Pharmacology 5th ed. p. 782). The persistence of sulphamoglobin in these patients implies that this substance cannot be so decomposed and that the HS cannot be excreted from the lungs. Probably the sulphamoglobin must be eliminated by the liver. Since methamoglobin disappears so much more rapidly it is unlikely that it is removed in similar fashion. Owing to its nature removal could scarcely occur in the lungs and it would seem not improbable that it can be reduced again to haemoglobin. If however this is correct it is difficult to understand why oxygen should appear to relieve cyanosis in patients who have methamoglobinæmia.

The detection of sulphamoglobin in the blood of the affected patients long after the disappearance of clinical signs of cyanosis points to the spectroscopist as being a much more delicate means of detecting poisoning from this group of drugs than the clinical observation of cyanosis.

CLINICAL AND THERAPEUTIC NOTES

In 3 of the patients (Nos. 1 to 3) the cyanosis was alarming but all recovered. The impression gained from these cases is that although the cyanosis appears serious danger to life is not great. Of the cases already reported which became cyanosed after the use of sulphanilamide or its derivatives only one (Frost 1937) has ended fatally. Though magnesium sulphate was not given to the patient during administration of the drug in Frost's case it is not stated whether the patient had had sulphates before coming under observation.

Further symptoms noted in our cases were nausea, headache and discomfort in the upper abdomen. In Case 17 where there was methamoglobinæmia mental confusion was a conspicuous symptom but it disappeared on stopping administration of sulphanilamide. Mental symptoms were a marked feature of Waterfield's case.

The treatment for alleviation of the symptoms depends on whether sulphamoglobinæmia or methamoglobinæmia is present. In the former case oxygen has little effect (as might be expected) but intravenous administration of saline and glucose relieves the cyanosis temporarily at least. If the patient's life appears to be in danger transfusion is indicated. If there is methamoglobinæmia oxygen appears to be of value. The cyanosis accompanying methamoglobinæmia disappears rapidly.

Before giving sulphanilamide a careful inquiry should be made to find whether magnesium sulphate or preparations containing it have been used owing to the common use of this substance to stop lactation.

SUMMARY

1 Administration of magnesium sulphate simultaneously with or within two or three days preceding administration of sulphanilamide gives rise in most persons to sulphamoglobinæmia. The formation of sulphamoglobin takes place very rapidly even after small doses of the drug.

2 In the absence of sulphates large doses of the drug are well tolerated but in a considerable proportion of persons doses of 1 to 24 grammes per diem result in methamoglobinæmia. Some patients may have an increased susceptibility to the drug.

3 The removal of sulphamoglobin from the blood is much slower than removal of methamoglobin. The former has been detected six weeks after administration of sulphanilamide ceased. The latter disappears in approximately 24 hours.

4 Spectroscopic examination of the blood is a more delicate means of detecting sulphæmoglobinæmia than clinical observation of cyanosis

5 Oxygen is of little value in treatment of severe cases of sulphæmoglobinæmia. If the patient's life is in danger blood transfusion is indicated. In methæmoglobinæmia oxygen appears to be of value

A CONTRIBUTION TO THE PATHOLOGY OF THE RHEUMATOID TYPE OF ARTHRITIS AND OF RHEUMATIC FEVER*

BY A G TIMBRELL FISHER, M.C., F.R.C.S. Eng

ORTHOPÆDIC SURGEON TO THE ST JOHN CLINIC AND INSTITUTE OF PHYSICAL MEDICINE LONDON AND TO THE LONDON COUNTY COUNCIL ARTHRITIC UNIT, ST STEPHEN'S HOSPITAL

ALTHOUGH, from time to time, contributions have been made to our knowledge of the pathology of the rheumatoid type of arthritis of unknown ætiology, (synonyms rheumatoid, chronic infective, atrophic, or proliferative arthritis), most of these have dealt with the later stages. The disease is rarely fatal per se and opportunities for post mortem examination in the acute or earlier periods are therefore rarely provided. Post mortem examination of patients who have succumbed to rheumatic fever is more often possible, but it is often observed that the joints of the heart is studied in detail and that the joints receive scant consideration. In the case of the rheumatoid type of arthritis, the classical pathological descriptions of Nichols and Richardson (1910) and of Strangeways (1918), and others, detailed as these are, are based to a large extent upon examination of material from the later stages of the disease. The pathological changes in such are complex since secondary degenerative or osteoarthritic changes are often superimposed, a theory of the cause of which will be put forward in this paper.

The work of Allison and Ghormley (1931) was based largely upon material obtained at operation upon joints affected with the rheumatoid and other types of arthritis at a somewhat earlier stage, and merits careful study. They drew particular attention to the "focal collections of lymphocytes" often observed in this disease and previously described by Hoffa and Wollenberg (1908) and by myself (1923), and claimed that these collections are a specific diagnostic feature.

A series of important papers has recently appeared from Klinge and Grzimek (1932). These authors are among those who maintain that rheumatic fever and arthritis of the rheumatoid and osteoarthritic types are different forms of the same underlying pathological process. It is my view that a principal cause of the confusion that exists concerning rheumatic

diseases is that we have neglected the Huntenan principle of basing our treatment upon a firm foundation of anatomical, physiological, and pathological knowledge. The present work is a sequel to former work on the pathology of the osteoarthritic and rheumatoid types of arthritis and upon joint physiology.

SOURCE OF MATERIAL AND SCOPE OF INVESTIGATION

My investigations have been carried out upon synovial tissues removed at operations during the last fifteen years upon patients suffering from the rheumatoid type of arthritis. These operations include the ordinary excisions and synovectomies in cases of long standing and, in addition, the newer method of lavage of the affected joints with normal saline or with antiseptic solutions combined with removal of portions of synovial membrane. The pathological changes in the articular cartilage and bone have also been studied, but as operative and post mortem material of this nature has only been obtained from the later stages which have been previously described by myself (1929) and others, these changes will not be described in this paper.

Arthrotomy and lavage is a valuable means of treatment in carefully selected earlier cases of the disease which have proved resistant to the usual medical and physical treatment, when the brunt of the disease falls mainly on one or both knees and when the articular surfaces are uninvolved or present early changes. It is of great value also in providing an opportunity for investigation of the joint tissues and fluids. It is a procedure which presents considerable advantages over mere aspiration, since the rheumatoid joint, even at a comparatively early stage, contains a variable amount of necrotic material due to fibrinoid degeneration of the synovial membrane and which it is impossible to remove through a needle or trocar, even when of large calibre. Many joints which give the sensation of fluctuation and which on clinical examination appear to be full of fluid, yield on aspiration but a moderate quantity, owing to the large amount of necrotic material present. It is for this reason that the operating arthroscope has proved disappointing in my experience. Occasionally, if conditions are favourable, arthroscopy enables a good view of the interior compartment of the knee joint to be obtained, but it possesses no special advantage over routine clinical and x-ray examination. The main drawback to the use of the

* Based on a lecture delivered at the St John Clinic on Nov 13th, 1936

arthroscope lies in the fact that the masses of necrotic material to which reference has been made obstruct the view and cannot be completely removed through the cannula of the instrument even after frequent irrigation. In many patients the symptoms have completely disappeared after arthrotomy and lavage and they have remained cured for periods as long as 12 and 14 years and in the majority there has been a most gratifying amelioration of symptoms. This method of surgical treatment will be described in detail elsewhere.

Bacteriological examination.—The research into the aetiology of the rheumatoid type is being carried out by Dr Hardy Eagles of the Lister Institute. The purpose of this combined research has been to correlate the pathological findings with examination of joint fluids and synovial membrane removed at operation for evidence of a possible virus aetiology and to investigate the possibility of a pathological and aetiological relationship between acute rheumatic fever and the rheumatoid type of arthritis. After suitable manipulation of the specimens and high speed centrifugation Dr Eagles has obtained suspensions which are indistinguishable from elementary bodies demonstrable in similar suspensions.

FIG. 3 (Case 1).—Rheumatoid type of arthritis. Section of synovial membrane ($\times 210$) showing small focal collections of cells under higher power showing giant cells of Aschoff type.

Barnard kindly provided material from autopsies for the investigation of the synovial changes in the arthritis occurring in the course of rheumatic fever.

EARLY RHEUMATOID ARTHRITIS

My first case is one of the rheumatoid type of arthritis of unknown aetiology.

For two years the patient an unmarried woman aged 38 had complained of pain and stiffness of both knees of moderate severity. She had also experienced occasional pain and stiffness of the neck. For two weeks before operation she had complained of severe pain stiffness and swelling of the right knee and difficulty in walking. No toxic focus could be discovered.

The right knee had a synovial effusion with painful limitation of flexion increased temperature over the joint and tenderness over the deep fibres of the internal lateral ligament. Radiographically the knee showed no osseous changes.

Operation.—Small incision on the inner aspect of the joint. Smears of synovial fluid taken. Small portions of the infrapatellar pad of fat were removed and the joint washed out with normal saline. No changes seen in the articular surfaces beyond very early pitting on the internal femoral condyle.

The sections of the synovial membrane from this case show proliferation of the synovial villi and of the specialised synovial cells lining the villi. There is degeneration of the superficial cells at one or two spots. In the deeper layers of the synovial membrane are several small focal collections of cells which are in the main perivascular (Fig. 1). The cells constituting the collections are lymphocytes and histiocytes and occasionally among these cells large histiocytes somewhat triangular in shape and resembling the giant cells seen in the Aschoff nodule of rheumatic fever can be recognised. In the region of these collection areas of focal hyaline degeneration of the connective tissue can occasionally be seen which often involve the adventitia of the blood vessels. Proliferation of the vascular endothelium is a prominent feature and in some cases the arteriole or capillary is completely blocked by endothelial proliferation. An important feature is the complete absence of the polymorphonuclear cell which is a feature in the forms of arthritis associated with the presence in the joint of pyogenic organisms. The bacteriological examination of the joint fluid and tissues was negative.

FIG. 2 (Case 2).—Rheumatoid type of arthritis. Section of synovial membrane ($\times 70$) showing large area of fibroid degeneration above and to the left and several focal collections of cells in the deeper layers.

from recognised virus diseases. Similar bodies have been found in the pericardial and pleural exudates and joint fluids from rheumatic fever. These suspensions have been examined for agglutination with rheumatic sera using the hanging drop technique. Tests have been carried out with material from rheumatism of the rheumatoid type and rheumatic fever. This aspect of the work will be described by Dr Eagles in a forthcoming publication.

It is proposed in this preliminary paper to describe shortly the *pathological aetiology* of the rheumatoid type of arthritis of non-specific or unknown aetiology and to compare the changes with those seen in the joints in rheumatic fever a few representative cases only having been selected for description.

Some of the rheumatoid group were private patients but the majority were patients at the L.C.C. Arthritis Unit, St Stephen's Hospital and the histological examination of the joint tissues removed from the latter was carried out at the Central Histological Laboratory of the London County Council. Prof. H. M. Turnbull and Dr. W. G.

FIG 4 (Case 3)—Rheumatic fever. Section of synovial membrane ($\times 120$). Above and to the left are several blood vessels showing fibrinoid degeneration of the sub intimal layer. Below and to the right are two Aschoff bodies with typical giant cells.

A LATER ACTIVE STAGE

The pathological histology of the rheumatoid type at a later, but still active, stage will now be described and comparison made with a case of rheumatic fever which shows many similar pathological features. In particular, attention is drawn to a peculiar form of degeneration of the connective tissues known as "fibrinoid" which has been observed in the lesions of rheumatic fever for many years, although its occurrence in the rheumatoid type has only been recently described by Klinge and Grzimek (1932). Perivascular collections of cells are seen, as before, but, in the cases to be described, giant cells of the Aschoff type are a prominent feature, not only in the case of rheumatic fever, but in the rheumatoid type of arthritis—a phenomenon which does not appear to have been described before in the latter disease.

In my second case of the rheumatoid type of arthritis the patient was a married woman aged 62.

Nine months before operation, painful swelling in the right ankle suddenly developed, followed two weeks later by similar symptoms in the right knee. She received electrical treatment for several weeks and the joints improved, but soon the left knee, the right wrist, and the metacarpophalangeal joints of the right index and second fingers became involved. All joints, except the left knee, responded to medical and physical treatment. No toxic focus could be discovered.

Operation.—Long parapatellar incision on inner side of left knee. The synovial membrane showed hypertrophy of the synovial fringes and was oedematous in places. Much fibrinoid material was present, not only in shreds in process of exfoliation from the synovial membrane, but free in the joint. Early pannus extended for a short distance over the lateral portions of the femoral condyles, but the articular surfaces were otherwise uninvolved. Synovectomy was performed and the joint irrigated with Dakin's solution. Bacteriological investigation of synovial tissues and fluid was negative. The infrapatellar pad of fat was chosen for microscopical examination.

Several large areas of fibrinoid degeneration (Fig 2) not only of the superficial area, but lying more deeply were clearly shown. At this stage of the disease it is usually to be noted that the synovial membrane is diffusely infiltrated with chronic inflammatory cells, principally lymphocytes, plasma

cells, and epithelioid histiocytes, in addition to the typical perivascular collections of cells previously described. In this type of case, giant-cells of the Aschoff type can usually be observed (Fig 3), if the smaller perivascular collections are examined, rather than the areas diffusely infiltrated with chronic inflammatory cells.

RHEUMATIC FEVER

The third illustrative case is one of rheumatic fever in a girl aged 9.

She was admitted to St Charles' Hospital a fortnight after the onset of illness with temperature and pain in right elbow which, however, ceased on admission. Pain and swelling of both ankles commenced three days before admission and the ankle joints were hot, swollen and painful. The temperature on admission was 99.8, the pulse rate 144, and respirations 26. The heart was not enlarged, but a mid diastolic mitral murmur was present.

Two weeks later, the patient became gravely ill with extreme restlessness and incontinence. The heart was now enlarged with canter rhythm and loud apical systolic bruit. The patient gradually sank and died. The post mortem examination by Dr Barnard revealed oedema of medulla, pons, mid brain, basal ganglia and parietal lobe of brain, rheumatic synovitis of sternoclavicular articulation, partially organised fibrinous pericarditis with Aschoff

FIG 5 (Case 5)—Rheumatoid type of arthritis. Section of synovial membrane ($\times 113$). Showing several lymphadenoid nodules some of which have a clear central area.

nodes in myocardium, rheumatic mitral endocarditis, oedema of lung with fibrinous pleurisy and congestion of liver and kidneys.

Sections of the synovial membrane of the sternoclavicular joint (Fig 4) reveal many of the specific histological features of acute rheumatism that have so often been described in connexion with the heart. Fibrinoid degeneration is a prominent feature (a) of certain of the synovial villi and of the surface of the synovial membrane, (b) scattered diffusely throughout the synovial membrane, and (c) in connexion with the inner coats of many of the blood vessels so that the wall appears to be thickened. Many of the capillaries are blocked by proliferation of the endothelial layer. Around many of the blood vessels are collections of cells in connexion with the adventitia. These cells are mainly large and small lymphocytes and epithelioid histiocytes, with occasional plasma and mast cells. Among the histiocytes are some giant cells which have two, three, or even more nuclei. These collections of

cells resemble therefore the Aschoff bodies seen in the heart

FIBRINOID DEGENERATION

Fibrinoid degeneration was apparently first described by Neumann in 1880 and again in 1896. In the latter paper he states that it is a substance which at first sight has the appearance of fibrin but which is in reality a form of degeneration of the connective tissue. It is usually stained a diffuse blue by the Weigert-Gram stain and is, like fibrin stained a deep blue by Mallory's phosphotungstic acid haematoxylin and red by Mallory's acid fuchsin aniline-blue. Klinge and Grammek (1932) state that it gives the fibrin staining reactions for the most part.

With Klinge I maintain that the fibrinoid degeneration of the synovial membrane here described is an important feature of the rheumatoid type of arthritis of so called unknown aetiology and that this form of degeneration is not therefore confined to acute rheumatism. In the latter condition it is seen not only in the synovial membrane but in the heart and in other regions affected by the disease. The degeneration affects principally the collagenous connective-tissue bundles and forms a striking histological picture. Dawson (1933) states that with Masson's trichrome stain it presents a fibrillar structure which stains a brilliant red in striking contrast to the vivid green of the normal collagen. My investigations show that this form of degeneration is therefore a characteristic feature of the rheumatoid type of arthritis of unknown aetiology except in the very early and in the more chronic stages.

OEDEMA OF THE SYNOVIAL MEMBRANE IN RHEUMATOID ARTHRITIS

Another interesting and important feature which appears to have hitherto escaped general notice is that at operation the synovial membrane can often be seen to be oedematous. This is well shown in the following case (No 4) which presents also other interesting features.

The patient a married woman aged 60 had complained of pain and swelling in the right knee for ten years of gradual onset. For the last three years, she has only been able to walk with two sticks and has gradually become worse. For eleven years, both wrists and hands have been painful stiff, and swollen. Has had eight children with

no miscarriages one had confinement with instruments and leucorrhoea for several years. Climacteric at age of 48. Bowels always constipated. All teeth removed eight years ago for severe pyorrhoea. Tonsils normal.

Operation.—Synovial membrane oedematous and general hypertrophy of synovial fringes. Synovectomy followed by irrigation of the joint with Dakin's solution. Some turbid free fluid present in the joint. Considerable destruction of the articular cartilage of the patella and condyles of the femur present with extensive pannus. The bacteriological investigation of the synovial fluid and fluid was negative.

Sections of the synovial membrane in this case show the chronic inflammatory infiltration with perivascular collection of cells and areas of fibrinoid degeneration to which attention has been already drawn. The sections of the synovial membrane show in addition the oedema which is often such a prominent feature in these cases. Near the surface of the synovial membrane are a large number of clear areas varying in size. These areas are surrounded by fibrinoid degeneration of the connective tissue and interspersed in this area are large numbers of giant cells which themselves often occupy spaces. These giant-cells vary in size some being of the typical Aschoff variety and having two or three nuclei while others have many nuclei and resemble foreign body giant cells. The giant-cells appear to be destroying the fibrinoid material, and many of the smaller spaces appear to be formed in this manner.

RHEUMATOID ARTHRITIS IN ITS LATER STAGES

The changes in the synovial membrane in more chronic cases of the rheumatoid type of arthritis of unknown aetiology constitute a very striking and in my opinion specific appearance and will now be described. They are illustrated in the following case (No 5) :—

Married woman aged 64. Onset of rheumatoid type of arthritis in right knee 2½ years ago during a time of mental and physical stress. No obvious toxic focus present but the majority of her teeth were removed shortly after the onset of the arthritis owing to pyorrhoea. Examination showed chronic arthritis of rheumatoid type of right knee—far advanced. Practically a flail joint and any attempt to flex the knee is accompanied by a sudden lateral displacement of a tibia with a painful jerk. Triple displacement of the tibia is present and there is ½ in wasting of the right thigh. Wassermann test negative. Arthritis of the rheumatoid type was also present in the metacarpophalangeal joints of both thumbs and in the proximal interphalangeal joints of both middle fingers. Owing to the gross destructive changes the joint was excised.

The sections of the synovial membrane from this case (Figs 5 and 6) demonstrate clearly the lymphadenoid nodules often with a clear centre that are such a conspicuous feature of this type of arthritis. The nodules are formed as follows: in the first place there is a perivascular collection of lymphocytes, histiocytes and plasma cells with an occasional Aschoff giant-cell as has been previously described. This is followed by proliferation of the vascular endothelium so that the clearer central area contains many cells of endothelial type interspersed with strands of fibrin (Fig 6). A close connexion of these lymphadenoid nodules with the blood vessels is clear on careful examination and seems to disprove the view of Allison and Ehrlicher that these nodules are not primarily perivascular. It has been suggested that the appearance of these nodules lends support to the tuberculous theory of origin of this form of arthritis. I cannot subscribe to this view as these

FIG 6 (Case 5)—Rheumatoid type of arthritis. Section of synovial membrane to show structure of central zone of a lymphadenoid nodule seen in Fig 5 ($\times 15$).

nodules never contain the characteristic tuberculous giant-cells and caseation is absent. The bacteriological investigation of the synovial tissues and fluid was negative.

In the later stages of the rheumatoid type, the synovial membrane and villi become fibrotic. Many of the blood-vessels are blocked, and, in some cases, there is a striking development of connective tissue around the vessels in the form of concentric rings (pericapillaritis diffusa of Shattock and Fisher (Fisher 1922-23)). As similar changes can be seen in the sub-articular blood vessels, it is clear that the nutrition of the articular cartilage and of the whole joint must be seriously impaired and this interference with the nutrition of the joint is probably the cause of the secondary osteoarthritic changes that so often supervene in the later stages of the rheumatoid type of arthritis. A large number of the specimens in the Strangeways collection at the Royal College of Surgeons of England demonstrate this fact very clearly.

There is evidence also that in some cases the arthritis of rheumatic fever, instead of disappearing, persists in a form indistinguishable from the rheumatoid type of arthritis and secondary osteoarthritic changes may eventually supervene.

COMMENTARY

The results obtained in the course of this investigation show that the pathological histology of the synovial tissues of uncomplicated forms of the rheumatoid type of arthritis of so called unknown ætiology and of acute rheumatism presents a similar and specific picture. The similarity of the pathological reactions in the synovial membrane in these clinical conditions supports the theory that they are manifestations of the same fundamental pathological process. Charcot (1881) wrote in this connexion "There are not two fundamentally distinct diseases but only two manifestations of one and the same diathetic state," and Hawthorne (1900) considered that the presence of similar subcutaneous nodules in the two diseases showed that they were intimately related. Of recent years, these subcutaneous nodules have been subjected to close pathological study by Coates and Coombs (1926), Freund (1928), Dawson (1933), Clawson and Wetherby (1932) and others, and it has been established that the pathological histology is identical in the two diseases. McEwen (1933) has studied by means of supravital stains the cells of the subcutaneous nodules of both rheumatic fever and rheumatoid arthritis and claims that the staining reactions of the cells in the two conditions are similar and differ from the cells in other granulomatous conditions such as syphilis and tuberculosis. He has found the same specific staining reactions in the cells of the synovial membrane in rheumatoid arthritis.

It is interesting to observe that the changes that have been described in the synovial membrane, both in acute rheumatism and in the rheumatoid type of arthritis in their early stages show a strong resemblance to the foci in the interstitial tissue of the myocardium in rheumatic fever first described by Poynton (1899) but further elaborated by Aschoff (1906), Carey Coombs (1911), and others. In this investigation, the pathological picture, the negative results of bacteriological examination of the joint tissues and fluid in uncomplicated cases, together with the absence of polymorphonuclear reaction in the synovial tissues—so characteristic of other forms of arthritis associated with the presence of pyogenic organisms—

is not in agreement with the hypothesis that the rheumatoid type of unknown ætiology is due to the actual presence in the joint itself of streptococci or other pyogenic organisms. It is a significant fact also that in a few cases in which streptococci were isolated from the synovial membrane, typical pyogenic membrane was observed, intensely infiltrated with polymorphonuclear cells, and it is important to note that definite toxic foci were present in these patients in contradistinction to the previous group. It would appear that in these cases secondary infection has been superimposed upon some other factor, the nature of which is still undecided. I am unable therefore, although some of my work is confirmatory of that of Klinge, to subscribe to his view that in uncomplicated forms of rheumatic disease the tissue changes are similar to those in septic diseases with a demonstrable exciting cause.

Are the peculiar and apparently specific histological changes that occur in uncomplicated rheumatic disease allergic phenomena associated with a focus of streptococcal infection? In this connexion it may be noted that Klinge has described similar changes in serum sickness. On the other hand, are they due to some other factor acting either alone or in conjunction with the streptococcus? The results of Schlesinger, Signy, and Amies (1935) tend to show that a virus might play some part in the ætiology of rheumatic fever. It would, however, be unwise to disregard the role of streptococci in rheumatic infection in view of accumulated evidence, and it is probable that both virus and streptococci are concerned in the ætiology. My research associate, Dr G. Hardy Eagles, will deal with these problems in a forthcoming paper.

In conclusion, I wish to express my indebtedness to Sir Frederick Menzies for kindly placing the resources of the London County Council hospital services at my disposal, to the Medical Research Council for financial assistance towards the expenses of the research, to Dr D. S. Sandiland, medical superintendent of St. Stephen's Hospital, Prof H. M. Turnbull, and Dr W. G. Barnard, chief histologist to the London County Council for much help, to Sir Leonard Hill and his other colleagues at the St. John Clinic and at the L.C.C. Arthritic Unit for their kind assistance.

ACQUIRED HÆMOLYTIC JAUNDICE

WITH UNUSUAL FEATURES

By E S DUTHIE M.B. Dubl. Ph.D.

ASSISTANT PATHOLOGIST, ROYAL HOSPITAL, SHEFFIELD AND
DEMONSTRATOR IN PATHOLOGY, SHEFFIELD UNIVERSITY

The following case observed continuously for nine months is recorded because unusual features in the blood picture made the diagnosis at first uncertain and because few similar cases have been described with autopsy findings.

CLINICAL RECORD

The patient a widow aged 70 was admitted to the Royal Hospital Sheffield, on Nov 15th 1935 with a history of breathlessness, palpitation, and pain in the legs and back for the past year. She also complained of a continuous nagging pain in the upper abdomen unrelated to food. About six months previously she had found that she was becoming pale and since then had been unable to do the housework. During the past three months she had had weekly injections of Campolon and had improved slightly the pain becoming less severe. She had always been pale but could remember no previous attack of anaemia nor was there any family history of it. She was slightly deaf.

Condition on admission.—She was a well built, well nourished woman with definite jaundice of the skin and sclera. She looked pale and ill and was very weak. Temperature 97.2° F pulse-rate 84; respirations, 20. Tongue clean and moist not atrophic. Mouth and fauces normal. Nails striated and brittle. Liver not enlarged. On percussion the spleen was found to be slightly enlarged but it was not palpable. The muscles over the left upper abdomen were somewhat rigid, and there was slight tenderness there. No enlargement of glands could be detected and the heart, lungs and nervous system were normal.

Laboratory investigations.—Blood examination showed:

Red cells	1,190,000	Polymorphs	70%
White cells	10,400	Lymphocytes	21.5%
Hæmoglobin	46	Mononuclears	2%
Colour-index	1.1	Eosinophils	0.5%
Hæmatocrit reading	83.4		
Reticulocytes	67		
Frølich's range	0.44-0.36		

Urine showed macro- and micro-cytosis. Almost two-thirds of the cells showed polychromasia and nucleated red cells were numerous. The van den Bergh reaction was indirect positive and the Wassermann reaction negative.

Several stools were examined and all were of normal consistence and failed to show blood by the benzidine test. The urine was dark brown and acid. The stomach juice was greatly reduced in quantity—not more than 50-60 c.c. being obtainable in three hours after histamine stimulation in the fasting state—but normal in composition. Radiography of the long bones showed nothing unusual. A leucocyte-tolerance test on Feb 7th 1936 showed an initial hypoglycaemia followed by a biphasic response resembling that found in von Gierke's disease but well within normal limits. It suggested that the glycogen had been mobilised with some difficulty. The fœterus index on Jan 8th 1936 was 10 units.

Clinical course.—The blood picture remained much the same for a month but the patient then began to improve. Campolon 2 c.c. daily was given from Dec. 18th 1935 onwards being supplemented by ferrous sulphate grains 3 t.i.d. until Feb 6th when Marmite alone was administered. The improvement continued until finally she was discharged on March 22nd 1936 with a hæmoglobin figure of 54 per cent and reticulocytes 8 per cent. Campolon was resumed before her discharge and she continued to receive campolon marmite and ferrous sulphate. She attended hospital once a fortnight for blood examinations the first made on March 31st showing a maximum of 60 per cent hæmoglobin and reticulocytes 8 per cent. She was not seen after this until April 27th when the hæmoglobin had fallen to 56 per cent and reticulocytes were 10 per cent. She said that she had been confined to bed by a recurrence of the pains in her legs and back.

The fall in hæmoglobin continued with a progressive rise in reticulocytes and she was advised to return to hospital but refused. On July 31st she was readmitted with the following blood picture—

Red cells	1,070,000	Polymorphs	9%
White cells	38,000	Lymphocytes	3%
Hb	25	Mononuclears	3%
Cl	1.7		
Reticulocytes	81%		

Price-Jones curve gave a mean corpuscular diameter of 155 with $v = 18.13\%$ and $s = 1.79$. The blood film showed polychromasia, macrocytes, microcytes and numerous normoblasts many with molliform distortion of the nucleus. Polymorphonuclears included many banded forms. No primitive cells. Indirect van den Bergh, 2 units.

She was again very pale and jaundiced and visibly distressed. Her mental condition was confused and she was at times comatose. The pulse rate was 90-100 and respirations 30. Temperature 99. Blood transfusions of 250 and 320 c.c. were given and she improved considerably her mental symptoms and respiratory distress disappearing. A further transfusion four days later was followed by an attack of dyspnoea but she recovered and remained well for six days, after which she again became extremely ill with a hæmoglobin value of 30 per cent. A further 250 c.c. of blood was given but she died next day.

POST MORTEM FINDINGS

Adipose tissue in fair amount everywhere. Heart enlarged (14 oz.). Musculature pale but no fatty striation. Aorta atherosclerotic with severe ulceration in abdominal portion. Lungs normal except for some oedema of the bases. Stomach and intestines normal. Liver enlarged (3 lb.) on section it had a mottled appearance due to areas of congestion. Microscopically the centres of the lobules were congested with haemoglobin in the central liver cells and iron pigment mainly at the periphery. Biliary tract normal.

Kidneys.—The left kidney was almost completely replaced by a large hydropneumothorax cyst. It was apparently of the floating type. The right showed a mild chronic nephritis with an iron-containing exudate (haemoglobin) in the tubules, and iron in the coils of the convoluted tubules. In the remaining substance of the left kidney iron was also present. The spleen was enlarged (1.5 oz.) and had numerous fibrous adhesions. The cut surface had a rich dark red pulp trabeculae and Malpighian corpuscles showed distinctly. A single small infarct was present on the left border. Microscopically the pulp was engorged with red cells the venous capillaries being moderately distended or collapsed. There was little iron pigment and only a moderate amount of haemoferritin; no fibrosis or increase of the reticulum. Erythroplasmacytosis common. Cells of the myeloid series not numerous. Malpighian bodies small. Many normoblasts and a few megaloblasts seen. No Gandy Gamma nodules.

Lymphatic system.—In the glands examined which were mainly thoracic and abdominal iron was found in moderate quantity in large macrophages lying in the sinuses. Considering the degree of blood destruction the quantity was not very great.

Marrow.—Rich red bone-marrow in the shafts of the humerus and femur but not in the tibia. Centre of the shafts occupied apparently by solid mass of dark red blood feeding at the periphery into a more organised and less darkly stained portion. On section the picture was very similar in both bones. Adipose tissue was almost absent being replaced by large collections of erythrocytes. In what appeared to be deeply congested capillaries and sinusoids. Here and there among the erythrocytes especially at the edge of the marrow were small active erythropoietic foci, or less often groups of myeloblasts. The walls of the sinusoids containing the erythrocytes were not clearly defined though with azan staining the cellular fibrils with cells could be determined apparently dividing the erythrocytes into groups. Megakaryocytes were numerous and evenly distributed. There were few nucleated red cells in these collections of erythrocytes whereas in other organs such as the liver and kidney nucleated red cells were usually conspicuous in the vessels. A similar lack of nucleated red cells was noted in the congested sinusoids of the spleen. It seems that even mechanism is at work which separates them out.

Ribs, vertebrae, and sternum showed similar pictures, except that the erythrocytes were fewer in proportion to the nucleated elements, and that they tended to be within well defined sinusoids and capillaries. Hemopoiesis was very active in these bones. Erythrophagocytes were fairly common. Megakaryocytes were numerous and well distributed.

No hæmopoietic foci were found outside the bones. The thyroid showed colloid changes with degeneration and calcification of the lower portion of the right lobe.

DISCUSSION

Fig 1 shows the hæmoglobin and erythrocyte and reticulocyte counts in the nine months before death. A fall in the reticulocytes was reflected in a rise in the first two, and vice versa. Since on the scale 5,000,000 red cells per c mm is equivalent to 100 per cent hæmoglobin, a rise in the colour index is indicated by the red blood cell curve lying below the hæmoglobin curve. Mean cell diameters measured by the method of Price Jones (1933) were on Dec 16th 7.25 μ , on Feb 28th 7.023 μ , on March 31st 7.075 μ , and on July 31st 7.155 μ . The curves on Feb 28th (when reticulocytes were only 4.5 per cent.) and on July 31st (when the patient was severely ill and reticulocytes were 81 per cent.) are compared in Fig 2. The curve made during the acute hæmolytic crisis is remarkable for the greatly increased variability, due mainly to the large numbers of macrocytes and microcytes. In the recovery stage these cells disappeared and the curve lay almost within normal limits. In form the curves are essentially similar to those given by Hawksley (1936), though in none of his cases was there any megalocytosis. The halo meter reading made during the first crisis was apparently incorrect. The large numbers of megalocytes seem to be equally balanced by the large numbers of microcytes and by the Price Jones method the mean diameter is almost normal. Fragility tests

the terminal attack especially in which the temperature was usually 97.0°-99.8° and prostration and mental symptoms were severe, the disease bore a certain resemblance to those cases described by Lederer (1925, 1930), and classified by him as being acute hæmolytic anæmia. There is, however, little

FIG 2.—Price-Jones curves in the recovery period (interrupted line) and during the terminal crisis (continuous line). The actual values are as follows. Recovery period Feb 28th, 1936. M.D. = 7.023, σ = 0.784, γ = 11.164 per cent megalocytosis, 0 per cent microcytosis, 1 per cent reticulocytes, 4.5 per cent. During the crisis July 28th, 1936. M.D. = 7.155, σ = 1.288, γ = 18.113 per cent megalocytosis, 13 per cent microcytosis, 15 per cent reticulocytes, 81 per cent.

FIG 1.—Graphs showing the result of blood investigations over the observation period.

showed little variation from normal. The highest result 0.475 per cent to 0.300 per cent was obtained by the method of Beebe and Hanley (1936), and is little above the normal standard they give. Unfortunately the mean cell volume measurements made were inaccurate.

The picture of a severe hæmolytic anæmia with raised colour index, high reticulocyte count, and normal or almost normal fragility, suggested acholuric jaundice. A similar case described by Reynolds (1930) had a colour-index of 1.3, a reticulocyte count of 95 per cent, and fragility of 0.40 per cent to 0.32 per cent. This was cured by splenectomy, making the diagnosis of acholuric jaundice almost certain. In

doubt that the anæmias he describes are merely acute attacks of acholuric jaundice—a view taken by Scott (1935), Murray-Lyon (1935), and Vaughan (1936)—and there is apparently no real basis for a separate classification. Whithy and Britton (1935) consider the good transfusion results in Lederer's anæmia to be a valuable diagnostic point, as is also the experience of other authors and of Lederer himself. In the present case the results of transfusion were unsatisfactory, recalling in some ways those obtained in two of Dawson's cases (1931). While the first two transfusions of 250 c cm and 320 c cm, given 13 days before death were followed by a definite improvement in the general condition, this was not maintained. A further transfusion 4 days later was followed by a crisis, the patient becoming more deeply jaundiced, but without the unpleasant symptoms seen in Dawson's last case. A consideration of the first attack, in which no transfusions were given, might suggest that they should be withheld as long as possible, though in the terminal attack the patient was much more ill. None of the other remedies given seem to have been useful. When they were first administered the patient was in a recovery stage, and their continuance did not prevent a second attack. Splenectomy, which was not feasible owing to the patient's age and general condition, was the only treatment likely to have been successful.

The autopsy findings agree with those of the six cases given by Turnbull (1936). Similar collections of erythrocytes were found in the marrow at autopsy, though he does not appear to be certain, especially in the last two cases, whether they always lay within definite vessel walls or not. The condition, while resembling hæmorrhage into the marrow, clearly differs from it, since active hæmopoietic islets are to be found all through the mass of erythrocytes, and there is no evidence of degeneration. The process as seen near the edge of the marrow fat, where such exists, is due to a congestion and widening of the marrow capillaries as the fat disappears, so that the

blood comes to be in sinusoids lined by the former capillary walls. This is confirmed by the fact that the congested sinusoids are about equal in area to the fat cells they replace. The engorgement of the splenic pulp is another feature that seems to be common to all cases.

SUMMARY

1 A case of hæmolytic icterus was observed for nine months before death. 2 Mean cell diameter measurements by the Price Jones method showed a high coefficient of variability reaching 18 per cent during the terminal crisis. Macrocytes and megalocytes were then equally balanced so that the mean diameter remained within normal limits. 3 Autopsy findings were enlargement of the liver and spleen the splenic pulp being engorged with erythrocytes. The femur and humerus contained a rich red bone-marrow all through their length composed mainly of sinusoids filled with mature erythrocytes and apparently derived from the pre-existing capillaries. The tibia was normal.

I should like to thank Prof. A. E. Naisb for permission to publish this case and for his help during the period of the observations. I also wish to thank Dr. Alice Stewart of the Royal Free Hospital London for making one of the Price-Jones determinations and for her interest and advice.

Clinical and Laboratory Notes

LYMPHOSARCOMA SIMULATING
DUODENAL ULCER

BY S. KEYS, M.R.C.S. Eng.

ASSISTANT PATHOLOGIST TO THE QUEEN MARY'S HOSPITAL
FOR THE EAST END, LONDON AND

W. W. WALTHER, M.B. Lond.

DIRECTOR OF PATHOLOGY AT THE HOSPITAL

This case shows under what a simple diagnosis lymphosarcoma may appear to the clinician. As a rule it is possible to diagnose general lymphosarcoma before the patient comes to the post-mortem room but in this case the disease showed symptoms referable to one organ only and the true nature of the condition was only suspected a few days before death.

The patient was a man aged 23, lorry driver by occupation. He was admitted complaining of abdominal pain of five years' duration. The pain was just below the umbilicus and passed to either side of the abdomen. At first it came on 1-1 hour after meals and lasted up to 2 hours. The attacks came on spontaneously and used to last for 3-4 weeks. There were free intervals of 3-4 months. Later the attacks had come on with great frequency and five weeks before admission he vomited for the first time. The vomiting became more frequent, usually occurring up to 15 minutes after a meal and it was of no difference to the pain. There was no hæmatemesis. Although the patient looked thin he did not complain of loss of weight. His appetite was good and his bowels were regular. He had never noticed signs of melæna. Occasionally he had attacks of flatulence.

The patient looked anæmic. The blood count was: hæmoglobin 41 per cent, red cells 3 million colour index 0.73, leucocytes 18,600 per c.mm. (polymorphs 77 per cent, lymphocytes 19 per cent, monocytes 3 per cent, eosinophils 1 per cent). There was no abdominal tenderness present and no other abnormal physical signs. Below the left angle of the mandible there was an oval mobile swelling 1 in. by ½ in. which the patient appeared to have had as long as he could remember.

A provisional diagnosis of duodenal ulcer was made and the patient was treated by drip transfusions and diet. Frequent occult blood examinations were strongly positive but a fractional test meal could not be estimated owing to the gastric juice containing abundant altered blood.

There was no improvement whatever. In spite of the drip transfusions the hæmoglobin fell although at times a rise of 1-3 points was recorded. He vomited on several occasions and each time the vomit contained altered blood. Three weeks before death a white cell count was 11,500 per c.mm. with the differential count of polymorphs 74 per cent, lymphocytes 25 per cent, and monocytes 1 per cent. A week before death the blood serum was noted to be icteric and gave a direct positive van den Bergh reaction. This suggested the possibility of malignant disease obstructing the flow of bile and on examination a tumour was discovered in the epigastrium. There was also general enlargement of the cervical glands. A fixed mass in the pelvis was found just before death. Altogether the patient was in hospital about seven weeks.

POST-MORTEM FINDINGS

Emaciated young man. Slight fullness of the thyroid gland. A few visibly enlarged glands in the neck. Abdomen distended. Tonsils not enlarged. The pericardial sac contained about 6 oz. of clear straw-coloured fluid. The heart was normal in size but the pericardial surface was covered by many patches of secondary growth. The chordæ tendinæ also contained a few nodules but the rest of the endocardium was normal. The lungs were congested, there were secondary deposits of growth in the right and left fourth ribs. The left lobe of the thyroid was normal, the right lobe was somewhat enlarged and contained a hard growth about the size of a walnut. The cut surface was hard and homogeneous.

The abdomen contained numerous loculated collections of faintly purulent fluid. The omentum was invaded by growth and was lying rolled across the epigastrium. All the abdominal lymphatic glands were greatly enlarged and matted together. A large mass of glands was present in the pelvis. The inguinal glands were enlarged. The stomach was infiltrated by growth and the mucous membrane showed numerous round ulcers with raised edges. One very large ulcer 1½ in. in diameter had completely perforated the posterior gastric wall and its edges were adherent to the liver.

The pancreas was one mass of growth. Glucose capsule contained a secondary deposit but the liver itself appeared normal. The spleen was also of normal size and looked healthy. Neither of these two organs contained macroscopic deposits of growth. Both kidneys were greatly enlarged and contained circumscribed neoplastic deposits of various sizes. There were a few enlarged glands all over the left ureter. The bladder was normal. Both testicles were normal. The brain and skull showed no abnormality.

MICROSCOPICAL EXAMINATION

Glands in neck—Filled with large round cells containing a well staining nucleus almost filling the cell. The cells are attached to a faint branching reticulum and show active mitosis. The very rare lymphoid tissue is compressed at the periphery of the gland. Bands of fibrosis can be seen traversing the gland.

Spleen—The mucous membrane shows partial destruction by sarcomatous cells. There is derangement of the alveolar structure of the mucosa. The mucosa appears to take place through the submucosa which contains an uninterrupted mass of sarcomatous cells. The peritesticular is partially invaded by growth.

Omentum—Complete invasion by growth.

Liver—The liver cells contain a coarse trabecular pattern but appear otherwise normal. The pattern

arteries are clear but the portal veins contain numerous malignant cells, which as yet show no evidence of invasion.

Spleen—The lymphatic element is replaced by large round cells with deeply staining nuclei. There is considerable congestion. The sinuses are filled with blood corpuscles and the sinusoidal walls appear normal.

Heart—Shows the growth infiltrating between the muscle strands and separating them. A coronary artery shows invasion of the adventitia, but media and intima are free of growth.

Thyroid—Shows invasion of the right lobe. The left lobe appears normal.

It is impossible in this case to determine the site of the primary growth, the enlarged gland in the neck being the only lymphatic abnormality to have existed for any length of time. It seems unlikely that the gastric symptoms could have been due in the first place to a neoplasm of such undoubted malignancy, for the patient would probably not have lived for five years.

It is interesting to note that generalisation of the disease occurred without alteration of the lymphocyte count. The raised polymorph count can be accounted for by the local peritonitis caused by the gastric ulceration.

We are grateful to Mr H W B Wright for permission to publish this case.

LYMPHATIC CYST OF THE MESENTERY AND VOLVULUS IN A CHILD

By REGINALD C JEWESBURY, D.M. Oxon.,
F.R.C.P. Lond.

PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT,
ST. THOMAS'S HOSPITAL, LONDON.

THE patient, a little girl aged 5 years and 8 months, was well until 2 years of age when she first complained of abdominal pain. Six months later she had another attack of pain accompanied by vomiting. At the age of 3 years and 9 months she was seen for the first time by a doctor. She then complained of acute umbilical pain and suffered from retching but did not vomit. Her pulse rate was 100 and her temperature 98.4° F., the only physical sign was some epigastric tenderness. The bowels were regular. Taking only fluids by mouth (with lemon and glucose solution to combat acetonaemia++) this attack was over in three days. During the attacks of abdominal pain she always adopted a kneeling position keeping her head bent down.

After this attack further medical advice was sought, a diagnosis of "acidosis" was made, and the appropriate treatment ordered. Following this she had several minor attacks for which it was not necessary to call her doctor. When aged 4½ years she had another fairly severe attack and was given glucose by mouth and per rectum. Two months later came another less severe attack and there was another one again after two more months' interval. At this period the urine showed coli bacilluria which responded to treatment. There were no further attacks for about 7 months, after which she again suffered from abdominal pain and vomiting, during this attack the pulse rose to 110, and there was some abdominal distension.

I saw the child for the first time on the third day of this attack, the abdomen was distended and rigid, but free from pain or tenderness. The pulse rate was 120 and the faeces was "abdominal", in fact the signs were those of acute obstruction with general peritonitis. Laparotomy was performed that

same day, as speedily as could be arranged, by Mr Max Page.

The whole of the small intestine was distended and deeply congested, as was also the whole of the mesentery. The bowel was completely obstructed after having become rotated on the mesentery. The strangulation was reduced by rotating the whole of the small intestine through three complete turns. In the cavity of the pelvis, and hanging slightly out of it, was a large, butter yellow-coloured cyst which at first looked like a distended bladder. The cyst was opened and about 15-16 oz. of thin milk-like fluid was evacuated, the cyst was situated in the mesentery close to its attachment to the small intestine about 2 ft. above the ileocaecal valve. The cyst wall was removed and tied off, and the abdominal wound closed, a drainage tube being left in.

The child died about four hours after the operation.

The following are notes from post mortem report by Dr S. Wyard.

The whole of the small bowel from the duodenojejunal flexure to the ileocaecal valve is enormously distended, the wall is plum coloured and there are numerous subserous and submucous hemorrhages. The surface is smooth and shining. About half an inch above the ileocaecal valve is a mark encircling the bowel obviously due to a tight strangling constriction. The caecal and ascending meso-colon is congested and shows many hemorrhages, the whole of the mesentery is also congested and hemorrhagic. About two feet below the duodenojejunal flexure is a surgical incision about four inches long, involving the mesenteric border of the bowel, the incision has been completely closed by sutures. Fluid removed from cyst, pale yellow and turbid, contained much albumin but no organised elements. The wall of the cyst on section appeared to consist of mesenteric tissue.

The time of origin of this cyst is doubtful, it may have begun when the child was two years old or it may have been congenital. Its recognition during the early stages was obviously difficult, but the recurrent attacks of abdominal pain and sickness were probably due to it. Refuge in the diagnosis of "acidosis" was a misleading factor in this case as it has been in others.

Lymphatic cysts of the mesentery are rare and not many cases have been recorded in children.

Bland Sutton (1922) comments on "a rare but interesting lesion known as chyle cyst of the mesentery." He compares them to omental hydroceles and ovarian cysts, and he states further that in infants or children, where many of them are found, these cysts are connected closely to the mesenteric border of the intestine and push their way between the layers of the mesentery. He concludes that these cysts are important, for they have caused fatal intestinal obstruction.

Swartley (1927) has written an interesting article on "mesenteric cysts" and describes the case of a girl, aged 7 years, which is very similar to the case which I now publish.

Eve (1898) reports the case of a cyst between the layers of the mesentery of the jejunum in a male child aged 11 weeks, and also in a child aged 3 years and 8 months, who had been admitted to hospital for "intestinal obstruction." Braquehaye (1892) classifies mesenteric cysts as follows—

1. Sanguineous cysts—usually traumatic and occurring as diffuse hemorrhages into the mesentery, into pre-existing cysts or into solid tumours.

2. Lymphatic cysts, comprising chylous and most of the serous cysts. These arise in the thoracic duct, in the chylous vessels or in the lymphatic glands of the mesentery.

3. Congenital cysts, chiefly dermoid, but occasionally cysts of the Wolffian body.

Lymphatic cysts are usually situated in the mesentery of the small intestine, usually near the spinal border,

but they have also been reported to occupy the mesocolon

Pederson (1928) has reported the case of mesenteric cyst in a girl aged 7 years which ruptured after an injury and in whom there was a history of previous intermittent attacks of abdominal pain Collins and Berdez (1934) report the case of a mesenteric cyst in a boy aged 4 years in whom a diagnosis of appendicitis had been made Friend (1912) states that cysts of this nature may occur at any age and in either sex In 52 cases the youngest was a child of 5 weeks and the oldest 80 years Raich (1890)

reports the case of a cyst between the two layers of the mesentery containing 6 pints of fluid which he thought had been caused by rupture of a chylous vessel of the mesentery

ROYAL SOCIETY OF MEDICINE

SECTION OF OTOTOLOGY

At a meeting of this section on May 7th the president Dr DOUGLAS GUTHRIE in the chair a discussion took place on

Otitis Media in Early Childhood (under 5 years)

Dr LE MÊTE (Paris) opening the discussion dealt almost exclusively with the kind of cases seen at 15 months of age and under based upon twelve years' experience at the children's hospital in Paris He said he had to include mastoiditis as no infection of the tympanic cavity occurred without infection of the mastoid too Infection extended from the pharynx to the mastoid The Eustachian tube was very short but in the infant its calibre was larger than in the adult; the mastoid antrum in the infant was also larger than in the adult and its external wall was a mere thin lamina of bone In the first stage of otitis the rhino-pharyngitis spread to the Eustachian tube and the change of colour in the tympanic membrane indicated its participation in the reaction Usually a few days after the performance of paracentesis the condition improved A more serious type of otitis was the primary purulent oto-mastoiditis To this condition Dr Le Mète gave the name unsuspected otitis as the symptoms instead of being localised in ear and pharynx, were systemic and general In an infant febrile with no apparent cause this type of mastoiditis must be suspected A third and less frequent type was an otitis mastoiditis and here a bone lesion was present requiring removal of bone A skanogram was useful in this type but every care must be taken in interpreting it Dr Le Mète had found it best to do the mastoid operation in two stages He wished generally speaking to insist that the surgery in infants must be done with great speed The routine in his hospital was first to incise the periosteum and a day or two later to remove the portion of bone

Dr T RICHIE RODGER (Hull) analysed the 599 cases of acute otitis media seen in children under 3 years of age at the Victoria Hospital for Children Hull since the ear and throat department was established there nine years ago Of these cases 249 were bilateral involving 818 affected ears 185 cases were of infants under one year of age 80 being bilateral infections There were 200 cases in children between one and two 86 of them being bilateral Of the 14 cases between two and three 83 were bilateral and 26 per cent required mastoid operation The bilateral condition was most frequent in the first four years of life and thus both ears should be examined even when the mother drew attention to one only and further thorough examinations

should be made at intervals during the whole time the patient was under observation Sometimes the appearance of the tympanic membrane was deceptive Probably many members could recall cases in which the temperature remained high or malaise continued despite myringotomy on one side and this was explained by a discharge from the other ear The incidence of mastoiditis requiring operation proved to be higher than was expected—namely 10 per cent of all infected ears at an age under one year In the third year it was 26 per cent in the fourth year 21 per cent The proportion of cases operated upon was sure to be affected somewhat by the personal views of the surgeon Every effort was made the present chronic otitis If conservative measures including removal of adenoids were not successful operation was recommended at a time which varied with the nature of the case When mastoid tenderness or high temperature did not abate operation was carried out without further delay A bilateral infection did not necessarily mean a more virulent form of case Otitis media was often associated with diarrhoea and vomiting and sometimes a coincident chest condition had to be excluded as the cause of the symptoms and signs before the mastoid was explored The incidence of tuberculosis in these cases had proved to be surprisingly small under 5 per cent in the series described; in a discussion on the subject in 1913 the incidence given was 50 per cent of cases in Edinburgh up to one year of age and 27 per cent in the second year of life Dr Rodger attributed this vast improvement to better sanitation and hygiene and the active educational work of child welfare and other clinics When tubercular otitis did occur the treatment must be radical

Dr J H LUNA (Birmingham) presented an analysis of the results of consecutive post mortem examination of the middle ear and mastoid antrum of 880 children 80 per cent of whom were aged 2 years or under The rest ranged between 2 and 14 years but the number over 5 years was small; 52.4 per cent of the children were found to have a purulent infection of the middle ear and mastoid antrum Of children dying in their first year as many as 62 per cent had otitis media in the second year 53 per cent in the third year 33 per cent otology might thus play some part in reducing the mortality The incidence of otitis media decreased progressively with the child's age; a slight rise between the third and fifth years might be related to school entrance Among 486 children in whom one or more acute otitis cases were examined post mortem a purulent infection was found in 162 (33.6 per cent) 150 had otitis media and 101 had no otitis In 200 cases examined histologically some had two or three kinds of virulent organism but the commonest was the streptococcus tubercle bacillus and

in 2 cases, the diphtheria bacillus in one; 238 infants under 2 years of age had severe diarrhoea and vomiting, either as a major complaint or a complicating factor. Dysentery organisms were found in 4 of these cases, 2 of which showed definite evidence of bacillary dysentery. Dr Ebbs did not attribute the gastro enteritis to otitis media but suggested that it was a serious factor in bringing about the fatal issue. A high temperature was nearly always associated with acute otitis media. Many patients showed their infection by a steep rise in the pulse rate, in certain infants, who maintained a temperature of 96° and 97° F for some days, the onset of the infection was marked by a jump in the pulse rate. The ears of all infants with pronounced gastro intestinal disturbance should be examined, drums should be freely incised but more extensive operation should be delayed when possible. In prophylaxis, breast feeding was very important. Only 2 among this series of autopsies were of infants who had been breast fed for an appreciable time. The danger of exposing these infants to respiratory affections suffered by adult contacts must not be forgotten. Dr Ebbs said that the results of his investigation pointed to a possible coöperative effort between the paediatrician and the oto-laryngologist which might be of very great value in the reduction of infant mortality.

Mr W STIRK ADAMS (Birmingham) spoke particularly of medical as contrasted with surgical otitis. Patients admitted to hospital because of something else who developed otitis caused considerable anxiety. Of 15 cases of secondary otitis developed in his hospital during the last two years 10 belonged to the diarrhoea and vomiting group. Of the infants who had diarrhoea and dysentery about a third died, thus the problem was very serious.

Mr C E SCOTT (Edinburgh) said that in the ear and throat department of the Royal Edinburgh Hospital for Sick Children, he and Dr R B Lumsden had treated 564 cases of suppurative otitis media between 1934 and 1936 inclusive, 145 of the children were under a year old and 419 were over one but under five years old. 154 required operation, of 136 who were subjected to the Schwartze operation 132 recovered. As to complications, 2 developed erysipelas, 4 measles, 4 scarlatina, 2 kidney trouble. The only intracranial complication was thrombosis of the lateral sinus (4 cases). Myringotomy was carried out 52 times, and 14 of those patients subsequently required a Schwartze, 22 per cent of the total number had a Schwartze done without previous myringotomy. They had been impressed with the value of the X ray picture of the mastoid, even in such young infants. Tuberculous infection of the middle ear was formerly much more common in young children than now, in the period under review the incidence was only 1.5 per cent of the total.

Dr LUMSDEN, referring to the occurrence of tuberculous infection of the ear, said that at a hospital 35 miles from Edinburgh the incidence was nearly 40 per cent, yet a careful inquiry showed that the disease was fairly evenly distributed between town and country dwellers.

Mr ERIC WATSON WILLIAMS (Bristol) said that the results of an analysis of a series of cases of mastoid disease made by him had suggested that the incidence was highest in children under a year old, the highest incidence of otitis media was in the first two years of life. Otitis media meant infection of the whole middle ear tract. There was no barrier dividing the tympanum from the mastoid, which became infected a few minutes after the tympanic cavity was diseased. If a child's condition caused it one sleepless night,

that was an indication for myringotomy. Quick operation was essential, a good average was a minute for each month of age—e.g., for a child of 7 months, a 7 minute operation. A 20 minute operation was a severe ordeal for a young infant.

Dr MCNAIR SCOTT said that, as a paediatrician, he was sometimes puzzled, when looking at the ears of infants, to know what to do. A child perhaps had an upper respiratory infection and a red ear drum, but showed no indication of being in pain. Should that ear be opened? If left without opening a certain number of infections subsided, in others general symptoms increased and the ear had to be opened next day. A red ear drum was commonly associated with pneumonia, but often no local intervention was required. Type 3 pneumococcus seemed to have a special predilection for the ear, and perhaps the drum should always be opened when the infection was of that type.

The PRESIDENT said that this subject had attracted too little attention from otologists. Otitis media was found in a large proportion of infants in hospitals, whatever the disease which brought them there, and at autopsy pus was found in the middle ear in many of them. The question arose whether this was a primary or a secondary condition, whether it was responsible for the malnutrition, pneumonia, or gastro enteritis from which so many suffered, or was a secondary phenomenon of comparatively slight importance. Ten years ago he had prepared a chart to show the extraordinary prevalence of otitis in infants, from 75 per cent to 90 per cent of infants, who died from all causes before completing their first year, had otitis. One reason for this high prevalence was that when the child was born there often remained fragments of embryonic connective tissue, such as filled the middle ear during embryonic life and became absorbed at about the time of birth. Portions might remain in the corners of the tympanum, however, and that embryonal tissue was very liable to become infected. The President asked why Dr Le Mée did the mastoid operation in two stages. He agreed with Dr Ebbs that the mastoid operation was seldom justifiable in children suffering from gastro enteritis. He did not think X ray evidence very useful in connexion with mastoiditis in children, but it might show the position of the lateral sinus, and its state of pneumatization.

Dr LE MÉE, in reply, said that since the mastoid operations were done in two stages at his hospital complications had been fewer, this experience was shared by Neumann. He used as an anæsthetic agent very cold water or ice applied to the back of the ear, he was sure it prevented the infant feeling pain.

Dr RITCHIE RODGER said that when he referred to speeding up the operation he was not thinking of the simple incision.

ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON.—At a special court of governors of this hospital on May 5th it was announced that the electrical and massage work which is carried out at present in a basement of the hospital is to be transferred to an adjoining property at a total cost of £8000, towards which Mrs H G Latilla has contributed £3750. A balance from a fund has reduced the sum required to £2000, and the governors are appealing for this sum. The new department is to be called the Latilla department of physical medicine and it is hoped it will be opened early next year. The transference will allow of a further extension of the X ray department at the hospital, and provide room for the installation of the Chauli apparatus presented by the Sussex branch council of the British Empire Cancer Campaign.

ROYAL ACADEMY OF MEDICINE IN IRELAND

At a meeting of the section of obstetrics on April 9th with Dr T M HEALY in the chair a paper on the treatment of

Varicose Veins in Pregnancy

was read by Dr EDWARD SOLOMONS. Sixty patients he said were selected at the antenatal department of the Rotunda Hospital for treatment of varicose veins by injection. They were chosen either on the ground that the veins would be easier to inject during pregnancy or because of symptoms such as cramps or swelling of the legs irritation of the skin pain in the veins or mental or physical discomfort. The condition was bilateral in 38 cases and unilateral in 22 while 1 had varicosities on the vulva as well. A history of phlegmasia was regarded as a definite contra-indication to treatment and in all cases where impairment of the deep circulation was suspected special investigation was made. The injection was done with the patient lying down and the leg slightly elevated thus the empty vein technique was used but a tourniquet was not required since only clearly visible veins were injected. The fluid injected was a sterile solution of quinine hydrochloride (0.260 g) and urethane (0.133 g) in 2 c.c.m. of distilled water made up by Parke Davis and Co. and the maximum amount given at one time was 2 c.c.m. usually distributed in four doses at different sites. In 15 of the 60 patients the veins were very large and an elastoplast bandage was applied to the whole leg below the knee immediately after injection. This was removed in three weeks time and in 7 patients no further treatment was required. In the other 8 further injections were given and the bandage again applied. The interval between injections was never less than a week and at least a fortnight was allowed between injections at the same site so as to let any reaction settle down. It was usually advised that injections should begin near the foot and work upwards but in these cases the veins most enlarged were injected first.

The results said Dr Solomon were very satisfactory but not all the women were free from subsequent discomfort. In 6 patients there was enough inflammatory reaction to necessitate treatment and 2 of these said they would have rather remained untreated. In 4 cases varicose veins of the vulva were treated by injection with very good results and in 2 dramatic relief was obtained from severe pruritus. It had only been possible to follow up 45 out of the 60 patients, but these had no complications in the puerperium and 3 had subsequent confinements without recurrence of the condition.

The CHAIRMAN asked why the treatment was stopped in the seventh month of pregnancy. He also asked whether Dr Solomon would limit injection to cases in which there was actual pain. He regarded the results as extremely good and believed that almost complete success might be expected among patients who could afford to have more rest during and after pregnancy.

Dr A H DAVISON said he understood that urethane gave rise to a lot of pain if the injection did not get into the vein. Had Dr Solomon any experience of sodium morrhuate?

Dr O DONNELL BROWNE asked Dr Solomon how he decided on the site of injection and said that varicose veins in the vulva were often very difficult to deal with.

Dr F DOYLE had seen a patient who had had injections for varicose veins and suffered great trouble in subsequent pregnancies. He was rather antagonistic to injections during pregnancy though they might sometimes be beneficial.

Dr G THIERRY was in favour of the injection of varicose veins after pregnancy but was not enthusiastic about injection during pregnancy. If it was done in the last three months he doubted whether much relief would be obtained. For varicosities of the vulva, especially during the early months it had a very definite place.

Dr J S QUIX said that if the treatment of varicose veins in pregnancy would allow a woman who would otherwise be more or less bedridden to get about he thought it should be used. But if the subsequent reaction or the period that had to elapse before recovery was such that no obvious benefit would accrue in the last two months of pregnancy, then it seemed that the treatment was unnecessary. In these cases one must consider not only the patient but also the doctor. If anything happened after the injection of a varicose vein the injection would certainly be blamed whether or not it had the remotest connection with what had happened.

Mr R M CORBET said there were apparently two classes of patient—the one with bad varicose veins who kept them after delivery and the one with bad varicose veins who showed no sign of them six months later. In the second type injection was probably unnecessary but in the first he was sure it was very useful.

Dr SOLOMONS in reply said that if he saw a case in the eighth month that he thought could be cured by injections in a fortnight's time then he gave a course but otherwise he only treated patients up to the sixth or seventh month. He did not attempt injections unless the veins were causing discomfort. One of the most severe reactions he had got was in a case in which he used sodium morrhuate. In patients who had very large veins especially near term injection treatment was foolish the treatment then was an elastoplast bandage. He thought that with the gradual advance of injection treatment sloughing would be much less frequent than at present. If there was any doubt as to whether one was in the vein it was best to withdraw the needle. He did not consider that patients who were bedridden derived any benefit from injections. Although certain veins might go away after pregnancy it had to be remembered that the next time the patients became pregnant they would suffer similar discomfort. The best time to inject was when the veins could be seen fairly easily.

Diabetes and Pregnancy

Dr H V TIERRE read notes on three pregnancies in a diabetic.

The patient came under his care in January 1933. She was aged 27 years married 15 months and pregnant for the first time. She had been under treatment for diabetes mellitus during the previous four years and two months and before becoming pregnant had been admitted to hospital in diabetic coma. She was receiving 70 units of insulin daily and despite this her urine was rarely sugar free and her blood sugar remained high. In April 1933 when 32 weeks pregnant she went into labour. The baby weighing 4 lb. lived half an hour. Five months later she again became pregnant and at 32 weeks gave birth to a baby weighing 7 lb. which died shortly after delivery. The third pregnancy began two months later and with a more stringent diet and larger doses of insulin proceeded to 32 weeks when labour was induced. The

baby when born weighed 8½ lb and appeared healthy, but died 48 hours after birth. At autopsy the cause of death was found to be suprarrenal apoplexy.

Dr Tighe said that nothing was observed in this case to support the view that the diabetic mother benefits from an additional supply of insulin from the foetus or that pregnancy produces a lasting exacerbation of the diabetes. While insulin has greatly lowered the maternal mortality, it has not proved so effective in reducing the foetal mortality. The causes of foetal death were poor control of the maternal disease during the later months, hydramnios, congenital abnormalities and over development of the foetus. Neonatal hypoglycaemia, following hypertrophy of the islands of Langerhans, had also been suggested as a cause of foetal death, but no enlargement of the islands was found in the baby which came to autopsy. Where there was dystocia due to the large size of the babies he preferred induction to Caesarean section.

Dr O'DONEL BROWNE knew of no recorded case of diabetes with three pregnancies. This case was characteristic in that the labours were premature, hydramnios was present in each of the pregnancies, the children were overweight, and while two were born dead the other did not survive long. It would have been interesting if Dr Tighe had been able to test the liquor amni for glucose—particularly if foetal urine had also been tested, for some authorities claimed that the presence of glucose in the liquor amni indicated its origin as a transudation from the maternal system since foetal glycosuria was extremely rare. As regards treatment, Dr Browne's view was that the diabetes should be treated irrespective of the pregnancy and that induction should be practised if disproportion was likely to arise owing to the size of the foetus.

Dr QUIN disagreed with Dr Tighe's view that there was no objection to a diabetic patient becoming pregnant. The results of pregnancy in diabetes were such that it should be discouraged unless means could be found for obtaining more fortunate results.

Dr MICKS referred to two cases of diabetes under his care in which labour had been induced, in both of which the baby had been strong and over the usual weight at birth, and the mother had done very well. In diabetes during pregnancy the urine should always be tested for ketone bodies, acute cases which went too far were liable to become quite uncontrollable. There was nothing to be gained by giving very large amounts of insulin.

Dr CORBET said that of two diabetic cases under his care during the last year one had had no trouble at all, whereas the other was fatal, the patient had been getting 90 units of insulin a day before she became pregnant. The lesson to be learned was that one must not allow oneself to do anything in connexion with the pregnancy while the diabetes was very severe. In these cases he always refused to induce labour. In his case that died, the patient came into labour herself, produced a macerated foetus, and died very quickly.

Dr TIGHE, in reply, said that the diabetes should be treated as a thing quite apart from the pregnancy, and the pregnancy should be allowed to proceed normally. As the children of diabetic women were not likely to be diabetic, there could not be any plea for sterilisation of diabetics on eugenic grounds.

Face Presentation

Dr DAVIDSON, master of the Rotunda Hospital, showed an X ray film of a primary face presentation,

and also presented an analysis of face presentation at the Rotunda for the previous forty years. There were 175 cases, excluding anencephalus, a frequency rate of 1 in 450. A quarter of the patients were primiparae. The foetal mortality rate was 8.6 per cent. In 134 cases the foetus was delivered spontaneously as a face presentation, 11 were treated by internal version, 6 by Schatz and 7 by Thorn's conversion to vertex. Forceps were applied to the face in 8 cases. Caesarean section was carried out in 3 cases, perforation was required in 4, and pubiotomy in 1. There were only 3 cases of impacted face, a frequency of 1 in 58. During the ten years 1926-36 there were 77 cases of face presentation of which 71 were born spontaneously as face presentations. If there was no disproportion the case should be left to nature and spontaneous delivery expected. Interference was required, however, if the face was arrested at the brim or on the perineum. With arrest at the brim conversion to vertex or preferably internal version should be adopted, with arrest on the perineum forceps might be applied. There were very few cases of major disproportion in this series, Caesarean section only being adopted on three occasions.

Dr O'DONEL BROWNE pointed out that the Rotunda incidence of face presentation, as given by Dr Davidson, was approximately half the incidence generally reported—namely, 0.42 per cent. He strongly advocated non-interference except in the relatively rare instance when the fact became impacted in the pelvic cavity as a mentoposterior. In these circumstances conversion to vertex, or if necessary internal version, was the treatment of choice. In the earlier stages of labour, he practised Schatz's manoeuvre and had been gratified by the results. He strongly condemned forceps delivery in cases of face presentation when the chin was posterior, quoting the maternal fatality rate associated with such treatment as 12 per cent, with a minimum foetal fatality of at least 50 per cent.

Dr CORBET said that Dr Davidson's figures were very good. He had only seen one case of true impacted face, and this was terminated successfully by a forceps delivery after partial rotation of the mother and the baby both lived. He had seen two face presentation cases where the neck was so stretched that the baby could not hold its head up. Most cases were diagnosed when the face was on the vulva. The conversion of a primary face presentation in a multipara depended very largely on the contraction of the uterus and on the actual position of the face itself. Internal version could be exceedingly difficult. It was safe to leave the vast majority of face presentations alone, but one must be sure that the face was the whole problem, and that the primary fault was not disproportion. One should not wait too long, but should watch the cases carefully so as to be able to interfere in time if interference became necessary.

Dr DAVIDSON, in reply, said he thought the reason why so few Caesarean sections were done was because face presentation was a very uncommon result of flat pelvis.

OPHTHALMIC HOSPITAL IN JERUSALEM—This hospital, which is under the auspices of the Venerable Order of St John, is planning large additions and an appeal is being made for at least £20,000 to provide funds for the erection of a new block to contain eight wards for paying patients and a new out-patient department.

REVIEWS AND NOTICES OF BOOKS

Handbook of Hygiene

By JOSEPH W BIGGER, M.D. D.Sc. F.R.C.P.I.
D.P.H. Professor of Bacteriology and Preventive
Medicine University of Dublin, London Baillière
Tindall and Cox 1937 Pp 400 10s 6d

THIS book is intended primarily for medical students but the author hopes with justification that it will also help the practitioner who is not a specialist in public health to play his part in the prevention of disease. For such readers the prevention of disease has a more direct appeal than the promotion of physical fitness and Prof. Bigger wisely approaches most of his topics from the former angle. Not that the promotion of health is neglected. The last chapter is entirely devoted to the assessment of normal health a pursuit which is one of the greatest contributions the general practitioner can make to the study and practice of preventive medicine.

About a third of the book deals with communicable diseases their character mode of transmission epidemic behaviour and prevention. Separate chapters are given to insects and vermin, to parasitic worms and to diseases of uncertain aetiology including rheumatism diseases of the heart and blood vessels anæmia nephritis diabetes and cancer goitre is briefly discussed in the chapter on water. Water food, ventilation disposal of waste environment—i.e. climate soil building construction heating and lighting—occupational hygiene and personal hygiene receive consideration in separate chapters. Maternity infant and child hygiene have brief but probably adequate attention. A separate and informative chapter is devoted to poisonous gases especially those used in warfare. Vital statistics are the subject of the first special chapter.

It is essential that a book on hygiene with which students have little practical contact, should be easy to read and that any dogmatic statements made in it should be capable of substantiation. This book answers these requirements. The author makes it clear whether he is expressing a personal opinion or an accepted thesis. The chapters on communicable disease are carefully put together and modern in their substance. The brief discussion of vital statistics is excellent for the purposes of the medical student. With the reservation made by the author himself—that occasional errors are inevitable in a book of such wide scope—it can be cordially commended to teachers and students of public health as well as to general practitioners.

Passive Vascular Exercises

By LOUIS G. HERRMANN, A.B. M.D. Assistant
Professor of Surgery University of Cincinnati;
Director of Vascular Disease Clinic of the Cincinnati
General Hospital London J. B. Lippincott Co.
1936 Pp 288 20s

DISAPPOINTMENT has followed most surgical procedures designed to save limbs affected by structural arterial disease. Any alternative method which offers a substantial degree of palliation by conservative means is therefore of interest and an authoritative evaluation of Pavaex therapy by its inventors deserves careful consideration by those who have to undertake the management of this prevalent disorder. Dr Herrmann's book has been divided almost equally into two parts: one historical and theoretical and the other practical; the applica-

tion of the method is described and hints are given on the selection of cases suitable for its use. The development of the therapeutic use of positive and negative pressures is traced back to the eighteenth century. This portion of the book though of great interest seems to us unduly long. The physiology of the circulation also might have been more briefly (and more accurately) described since the success of Pavaex therapy depends on the precise degree and rhythm of the changes in pressure required to produce the best results.

The clinical section of the work gives the impression that the author has based his opinions upon theoretical considerations rather than upon the results of treatment. He states clearly the contra-indications to the method—spreading phlebitis infection and extensive thrombosis of the small vessels and he advocates its use in embolic obstruction of main vessels. It is well known however that the risk of gangrene in a case of main vessel obstruction is in any case comparatively slight whereas Dr Herrmann gives numerous examples of gangrene due to small vessel obstruction which have been amazingly improved by Pavaex therapy. There seems to be no doubt that this is a valuable aid to conservation in the treatment of threatened gangrene, but the book fails to indicate clearly the clinical criteria whereby those cases may be selected which should derive most benefit from it.

1 Oral Diagnosis and Treatment Planning

By KURT H. THOMA, D.M.D. Charles A. Brackett
Professor of Oral Pathology Harvard University
London W. B. Saunders Co. 1936 Pp 370 25s

2 Oral Diagnosis and Treatment Planning

By S. C. MILLER, D.D.S. and Twenty-two Contribu-
tors London J. and A. Churchill 1937
Pp 620 30s

IT is unusual to find two books published within a few months of each other having the same title and covering so closely the same ground. Prof. Thoma's book being by one author has the advantage of a continuity which works written by many contributors often lack. It is essentially a book of diagnosis and pathology is reduced to a minimum. The salient feature of the book is the description under various headings of the method of systematic diagnosis: the chapters on general physical examination laboratory tests and radiology give the practitioner sufficient information to keep his knowledge up to date and to enable him to correlate the various methods of diagnosis. The remainder of the book is devoted to a clinical study of the various dental and oral diseases. The common conditions familiar to every dentist are described as well as the more unusual oral ones which may give rise to some difficulty in diagnosis. The numerous illustrations many of them in colour deserve high praise.

2. Mr. Miller's work is more limited in scope. It deals chiefly with dentistry proper and discusses such aspects as caries, periodontal disease, bridge work, orthodontics, and denture design. It is more practical if more diffuse than Prof. Thoma's book. Some of the chapters are excellent such as that on surgical conditions by T. Blum and K. Ions of the hard tissue by A. Walker. The three chapters on periodontal disease show how firmly the concept of traumatic occlusion or as it is now termed traumatic occlusion is held in

America and how much it has influenced treatment. According to this book almost the whole treatment of pyorrhœa consists of correcting this hypothetical malocclusion which is regarded as the chief cause of the disease. Infection is only a secondary factor and does not appear to call for any special treatment. Extraction is only advised for teeth denuded of their periosteum to the apex, and gingivectomy is held to have but a limited application. The large number of illustrations are mostly good and the book is well produced. For reference purposes both of these books will be found useful though we must confess to some doubt as to how far they are likely to help the dentist in planning his treatment.

Synopsis of the British Pharmacopœia

Thirteenth edition. With addendum, 1937. By H. WIPPEL GADD, Barrister at Law, Middle Temple and Western Circuit. London: Baillière, Tindall and Cox, 1936. Pp. 200 + 12. 3s.

THIS useful little book has been brought up to date by the introduction of a twelve-page leaflet dealing with the Addendum, 1936, to the British Pharmacopœia, 1932. All the important modifications of the text of the Pharmacopœia have been included with the addition of certain changes in the Poisons Rules. Some difficulty will be experienced in applying to the main text of the synopsis the alterations given in the leaflet. It is to be hoped that an entirely new edition will be forthcoming with these alterations included. The remainder of the leaflet will be found useful as a source of speedy reference to the more important features of the new drugs and preparations of the Addendum.

Meditatio Medici

A Doctor's Philosophy of Life. By W. CECIL BOSANQUET, D.M. Oxon., Fellow of the Royal College of Physicians, formerly Fellow of New College, Oxford. Aldershot: Gale and Polden, 1937. Pp. 162. 7s. 6d.

THE aim of philosophy, according to Herbert Spencer, is to make science "a system of completely unified knowledge." William James defined it more brightly as the response to the "desire to attain a conception of the frame of things which shall on the whole be more rational than the somewhat chaotic view which everyone by nature carries about with him under his hat." Judged by these standards Dr Bosanquet's little book has certainly a claim to contain a philosophy. His condensed and objective summary of general scientific knowledge is written with a remarkable sweep and elegance. It is not clear why the title "meditatio" should have been chosen for we have come to apply the term to a highly individual mental act and the essay is about as impersonal as it well could be. Perhaps the author wishes to convey to us that any attempt to make a "frame of things" must in the end be a personal construction. And with all his efforts at self-elimination Dr Bosanquet's "Weltanschauung" gives us in reflex something like a portrait of his mind—in dry point perhaps—but none the less arresting in its finish and poise. In so far as he can be referred to a school he appears to lean to the doctrine of Heraclitus, to whom the central fact of the universe was that all things change, and as with most of those who are preoccupied with the mutability of things there is an undertone of pessimism to his thought. This does not prevent his summing up of things from being on the whole both just and sympathetic.

It is only when he treads on the treacherous ground of sociology that he makes an occasional false step—for example, his statement that under modern democracy "Freedom of labour is rigorously restricted in order that the clever and efficient may be duly handicapped to the level of the idler and the weakly." This is the sort of "loose stuff" off which it is easy to score.

Organic Chemistry for Medical Students

Second edition. By GEORGE BARGER, M.A., D.Sc., LL.D., F.R.S., Professor of Chemistry in Relation to Medicine in the University of Edinburgh. London: Gurney and Jackson, 1936. Pp. 251. 10s. 6d.

IN the preface to the first edition of this book, which appeared in 1932, Prof. Barger explained that in his view "the chief reason for including organic chemistry in the medical curriculum is to provide a basis for biochemistry or chemical physiology and pathology." With this guiding principle in mind he has passed lightly over some of the more important types of syntheses employed in organic chemistry, and has laid greater emphasis upon those aspects of the subject which are of more immediate biological interest and which are likely to be of use to the medical student in his later studies, the text more over is replete with somewhat out of the common facts and observations calculated to stimulate interest. The chief alteration in the present edition is the bringing up to date of the salient facts concerning the chemistry of the hormones and vitamins. The size of the book remains the same as before but there is a welcome reduction in price.

Elementary Human Physiology

By SHERBURNE F. COOK, Associate Professor of Physiology, University of California. London: Harper Brothers, 1936. Pp. 539. 12s. 6d.

THIS attractive volume is stated to be designed for students who require a less advanced treatment of the subject than do medical students. The author's estimate of his work is too modest. It is true that it falls just short of the type of text-book one recommends as being thoroughly adequate for a medical course, but many teachers of physiology would be relieved if they could be assured that every student in their class had a complete grasp of its contents. Prof. Cook's book must not be confused with the excellent short ones which present physiology to the completely uninitiated. It is straightforward physiology, set out in such a plain way that one cannot fail to visualise the functions described or to understand the principles underlying them. It is a live treatise, written on the assumption that the reader has a scientific training and a critical mind. The book will make some wonder if many of the older texts, which run through edition after edition in order to be kept up to date, have not served their period of usefulness. For this work is a real revelation of what can be done by making a completely fresh start and presenting physiology as it is to-day, rather than by regarding new knowledge, which sometimes strikes at the very foundations of a subject, as in the nature of an addition to what is already known. The pictures and diagrams are refreshing, instructive, and not dictated by tradition. The coherence and almost ruthless elimination of irrelevancies in this work make it an excellent foundation for any course of study comprising physiology.

THE LANCET

LONDON SATURDAY MAY 15 1937

SHALL I GET BETTER?

AMONG many letters praising the articles on prognosis which appeared in these columns between 1934 and 1936 we had one from a practitioner who hoped they would soon cease to appear. Pressed to explain why, he wrote: 'In a large practice one has not a great deal of time for reading and I am more interested in diagnosis and treatment of patients I see every few days than in knowing what is going to happen to them perhaps many years hence. Life seems too short for the leisurely atmosphere of prognosis to appeal to me. This critic had assumed without justification that the authors would deal only with remote and not with immediate prognosis. But the main interest of his comment lies in his conception of the doctor as concerned with the cross-section of the patient's disorder at the time of the consultation rather than with any serial story of its manifestations throughout life. Unfortunately many doctors must perforce restrict their horizon in this way if they are to get through their daily round. But such an attitude is dangerous if only because unless the practitioner makes a mental picture of the probable course of the disease the course of treatment he prescribes may be unwise or at best unnecessary. In the words of Hippocrates he will carry out the treatment best if he know beforehand from the present symptoms what will take place later.' Moreover it must not be forgotten that to the patient diagnosis and treatment are merely the technique of his adviser used as means to an end. It is with the end alone that he himself is deeply concerned and to him the prognosis is the essence of any medical consultation. Indeed all his questions (e.g. 'What is the matter with me? What can you do for me?') are really designed to elicit the answer to one much more urgent which he hardly dares to frame lest the response should shatter his confidence. Shall I get better and soon enough not to endanger my livelihood or (on a higher plane) the completion of the work I have in hand?

This in relation to every patient whose indisposition is not trivial is the real problem confronting the practitioner day by day. All his energy is bent to its solution though he may not realise it. And since the most potent agent at the doctor's disposal is his power to give the patient confidence he cannot afford to ignore or disregard this unspoken desire to know something of what is likely to happen. Not that any statements made need be specific or unguarded to satisfy the patient requires much less definite information than might be expected. His need for reassurance is great and he will not only snatch at a straw

of hope but will gain support from it so buoyant to him, as its fabric. Even when the diagnosis is obscure and the treatment expectant such negative conclusions as an experienced clinician may safely draw will often suffice to give not only the patient but his friends the help they need. Even when it is not possible to say as it quite often is 'you are going to get well,' the doctor may be able to recognise, deep below the surface the particular phobia which is a torture and to remove it by an assurance for example that whatever the trouble is it is certainly not cancer. So twisted and illogical are our subconscious fears that a man may live contented for months suffering from a disease far more fatal than the dreaded one. An example recently before us was a woman whose slow recovery from an atypical pneumonia led to suspicion of tubercle. She would hardly consent to go to a chest hospital for observation and radiography so great was her fear of contracting the infection. A temporary improvement gave her a respite and when soon afterwards a thoracic growth was diagnosed she was so much relieved at the exclusion of tubercle that she submitted cheerfully to a course of deep X ray treatment enjoyed to the full the relief from symptoms it produced and when she became ill again remained hopeful of another remission until her peaceful death.

Similar stories will occur to all of us. They are relevant to discussions on prognosis in so far as they show that the patient's attitude to any disease is coloured by his previous impressions of the prognosis it carries. Often these impressions are incorrect or distorted and hitherto the family doctor has not had any convenient means of reference to authoritative opinion. The series of articles on prognosis of which the second group is published this week in volume form was designed to fill this gap. No attempt was made to cover the whole ground of medicine and surgery. The invited authors dealt only with subjects on which they felt they had something to contribute based either on wide experience or on a special study. But we have reason to think that the notes in each of the selected subjects will provide at best a safe guide to prognosis in individual cases and at least a foundation on which more accurate estimates can later be built based on statistical data.

PRECAUTIONARY ENTEROSTOMY IN APPENDICITIS

ALMOST all deaths from appendicitis are preceded by diffuse peritonitis and the mortality of this condition is estimated at 25-40 per cent. F. C. CONNELL points out that such deaths should be attributed to septic peritonitis rather than to the appendicitis from which it originates and he argues that as death from peritonitis is preceded by distension and ileus and as the treatment of established ileus is unsatisfactory, we should try to prevent distension, ileus and death by prophylactic intestinal decompression and enterostomy at the time of the appendectomy. This interesting suggestion is made in a brief editorial article and

he does not bring forward evidence in support of it other than the statement that it seems to reflect a growing opinion.

When such a procedure is contemplated a number of considerations arise. The first is that when one is operating for appendicitis it is impossible to estimate accurately the extent of the peritonitis without subjecting the patient to the serious risk of further spread of the infection within the abdomen. If we hold to the time-honoured dictum of MURPHY to "get in quick and get out quicker," if we believe this advice to be of the utmost importance in our operation, any such investigation will be precluded. Secondly, how far would an opening in the intestine be valuable? We do not know whether there is greater risk in encouraging the intestine to move than in fostering the abolition of peristalsis in an attempt to localise the infection. We do not know whether more poison is absorbed from the mucosa of the reflexly immobilised intestine or from the serous lining on its exterior. We do not know, in fact, whether it is better to allow the unaccustomed stagnation of intestinal contents to persist or to run the risk of some increase in the area of peritoneal infection by encouraging an action of the bowels. Then again the ileus concerns the intestine in the region of the infection. It is from this pathologically changed gut that any absorption of toxin is likely to take place, but every surgeon who has performed enterostomies knows how useless and ineffectual it is to make an opening in such bowel. There is no discharge from the stoma until or unless the peritonitis subsides, indeed such a discharge is a sign that the patient is likely to recover, just as an action of the bowels in cases of peritonitis has almost from time immemorial been held to herald recovery. Hence an enterostomy, to be effective, would have to be made above the region of peritonitis, and where this is will be only a guess if the least possible exploration is carried out, as seems advisable. Such an enterostomy would do nothing to drain away the stagnating, decomposing, and poisoning contents of the paralysed segment of intestine. It is more likely to give exit to harmless intestinal content and lead to loss of fluid which the patient can ill stand.

These reflections are no more than inferences from the known pathological condition of the peritoneum and intestine in diffuse peritonitis and from the practical results of enterostomy. The question has almost certainly to be judged upon such considerations because we have no way of measuring the degree of toxæmia caused by absorption from the peritoneal surfaces or intestinal lumen. Without a technique for investigating such problems we cannot, for example, claim that enterostomy diminishes the amount of toxic substances circulating in the blood. Clinical impressions of the course of appendicitis in patients with enterostomy may well be erroneous because we have no means of evaluating the primary degree of peritonitis. Probably most surgeons would agree that the difference between the course of the disease in those with an enterostomy and

those without an enterostomy is in no way striking, and many would say that it is difficult to detect. But if there is a definite feeling that good results may arise from drainage of the intestine, despite its many disadvantages, there is obviously a case for testing this method by such clinical observations as we are able to make.

FOUR PHASES IN SYPHILIS

THE differentiation of the venereal diseases from each other took long to achieve. At the end of the eighteenth and first half of the nineteenth century the views of medical authorities on their nature and the degree to which they were spread by contagion were so hopelessly confused that syphilis and soft chancre and even gonorrhœa were not really defined as separate entities, and the "mercurial disease" was regarded as a far more serious condition than the symptoms for which the metal was prescribed. Even such a careful observer as JOHN HUNTER (1728-93) is said to have regarded gonorrhœa, syphilis, and soft chancre as the same, and to have denied the existence of visceral, tertiary, and hereditary manifestations. The whole tendency at that time was to belittle the effects of venereal infection and it is to the strenuous efforts of PHILIPPE RICORD (1800-89) that we owe the clear conceptions that have been established and have persisted almost unchallenged to the present day. As a result of his clinical and pathological studies he wrote a book, "*Leçons sur le Chancre*," which appeared in 1858, in which he formulated the doctrine that "*le drame de la syphilis se divise naturellement en trois actes ou périodes*." Rightly or wrongly this doctrine has now held sway for some 80 years and has proved its value both as a basis for teaching and in planning and conducting treatment. Prof JOHAN ALMKVIST of Stockholm has challenged¹ this classical conception of the pathology of syphilis. His argument is based almost entirely on histological studies to which he has devoted a large measure of his spare time since his appointment to the professorial chair in Stockholm in 1911. These investigations have led him to formulate certain precepts, which he sets out and supports with a wealth of illustrative photomicrographs. He claims that in each kind of tissue spirochætes bring about a histological reaction which is characteristic of the tissue in question, but different from the reaction produced in other tissues. The changes attributable to the syphilitic process in each kind of tissue are, according to ALMKVIST, uniform throughout the whole course of the disease, they are the same in recent and in old standing syphilis, and cannot be separated into three stages. Further, the different clinical manifestations of the syphilitic lesions are not due to differences in the reactions between the spirochætes and the tissues, since the tissues react uniformly throughout the whole course of the disease, but rather to such factors as the varying location of the spirochætes, differences

¹ *Acta derm venerol Stockh* 1937, 18, Fasc. 1. *Brit J Derm* 1937, 49, 1.

in the degree of immunity toxin antitoxin reactions, nutritional disturbances and so forth.

ALMKVIST postulates that broadly speaking there are only two types of reaction to the spirochate demonstrable by microscope—proliferative and degenerative. In the epidermal layer there is a proliferation of new cells of the same type as the mother cells with resultant hypertrophy of the rete Malpighii and the interpapillary epithelial processes which is the process mainly responsible for the initial chancre. The connective tissue responds similarly but here we find a more varied microscopic picture for new cell elements—plasma cells round cells, and lymphocytes—make their appearance and the resulting histology is therefore not always the same. For this type of reaction ALMKVIST proposes the term infiltration and as connective tissue is more widespread than any other in the body we find it as we should expect the commonest of all syphilitic processes throughout the entire course of the disease. Lymphatic vessels and blood capillaries are similarly stimulated to proliferate but the specialised and more highly organised cells such as the nervous muscular hepatic and renal cannot do so. Their connective tissue framework will react as described above they themselves however in course of time either in response to the toxic effects of spirochatal invasion or as a result of circulatory deprivation undergo late degenerative alterations. Infiltrative and degenerative changes are similarly observed in the walls of the larger blood vessels and may later account for the symptoms of aneurysm and arterio sclerosis. Two other subsidiary changes have to be noted—the pustular and necrotic. The pustule is less commonly met with than formerly. It is never a primary reaction but always occurs in previous infiltrations of the connective tissue. When well developed it is the histological background of so-called malignant syphilis. Necrotic changes are similarly superimposed. In his conclusions it would seem that ALMKVIST is still inclined to favour a phase or period progress of the disease. In place of the established division into three stages he now proposes a classification on a real pathological basis into four stages.

1 Initial or humoral stage when the spirochetes are in the blood (the disease is held to be constitutional from the outset) and other fluids and in the chancre. In this stage therefore are included the former primary and secondary periods of Ricord with chancre, fever, splenic enlargement, albuminuria and so forth.

2 Hematogenous syphilis. All the organs and tissues especially the lymph glands are now invaded by the spirochetes conveyed to them by blood or lymphatic channels. (It seems to us that this phase on the author's own showing is practically the same as the preceding.)

3 Scrupiginous or creeping syphilis. From a former infiltration as a focus, the spirochetes creep or insinuate themselves into the interstices of tissues in their neighbourhood initiating visible cutaneous changes and hidden transformations at a deeper level. Clinical examples of the former are the old tertiary circinate syphilide the condylomata and various forms of mucous occurrence—gummatous syphilide of the scalp pustular syphilides and gummatous which may be either superficial or deep.

4 Late degenerative syphilis in which are included all the various forms of cerebro-spinal lues—tabes G.P.I. and so forth—and the vascular lesions which develop in the walls of the larger blood vessels.

The new conception excludes such theories as the allergy of von Pirquet as applied to syphilis and according to ALMKVIST renders the three-stage doctrine of RICORD no longer tenable. Time will show whether these elaborate histological studies will prove a sufficient reason for so radical an alteration as is proposed especially in view of the fact that on the author's own showing phase 2 differs very little from phase 1. There can be no doubt however that that histological approach is one to which insufficient importance has been attached in the past and that the new ideas elaborated on this foundation by ALMKVIST will materially assist the labours of those engaged on the many problems of prognosis and treatment in all parts of the world.

IS PASTEURISATION HARMFUL?

It remained a very good beverage but it did not remain milk.

THUS LORD CREANWORTH in the Lords debate on pasteurisation reported in our last issue his opinion was forcibly supported by the Bishop of Norwich when the debate was resumed (see p. 1166) and is widely shared in the medical profession. But how far is it justified? Of the published evidence very little is convincing and much is contradictory. In elaborate experiments¹ at the National Institute for Research on Dairying rat families tended to die out on a diet of sterilised milk (and biscuits) while those on pasteurised milk showed some inferiority including signs suggesting deficiency of vitamin B₁. Such results however require very cautious application to human nutrition and it will be easier to form a judgment from the more comprehensive inquiries lately made at the same institute and at the Rowett Institute on behalf of the Milk Nutrition Committee which was established in 1934 with Lord Astor as chairman. The object of these inquiries² has been to determine the effect of commercial pasteurisation on the various constituents of milk and also to decide whether a pint of pasteurised milk is equal to a pint of raw milk from the nutritional standpoint. Their answers³ are that the changes caused by pasteurisation are not serious. Thus moderate heat does not (as has been alleged) affect the nutritional available ilot of the calcium and the phosphorus or the biological value and true digestibility of the nitrogen. Neither vitamin A nor its precursor carotene is damaged by pasteurisation. There is some loss of vitamin B₁₂—probably in the B₁ fraction—and about 20 per cent. of the vitamin C disappears if (as is usual) the milk has been exposed to light before heating. The committee does not propose to discuss the bearing of these laboratory results on human nutrition until it has published complementary observations on calves and school children. But they already show that milk suffers no damage by pasteurisation that is important compared with the risks of drinking it raw.

ANNOTATIONS

PERSPECTIVE AND POISE IN PRACTICE

PERSPECTIVE—defined by Webster as the capacity to view things in their true relations or relative proportions—was the text of the annual oration delivered before the Medical Society of London last Monday by Dr R A Young. He said that his interest in perspective as applied to medical problems had been stimulated many years ago by the assessment of a distinguished physician by one of his pupils, himself a man of great practical ability. The pupil had summed up the teacher, for whom he had a real admiration, as having "very wide range but no perspective" a man, that is, whose standards of the relative importance of details were often faulty. His opinion on a case was learned but unhelpful in practice, he could not see the wood for the trees. In medicine as an art, said Dr Young, we want an horizon and the idea of a vanishing point, or at any rate a point of focus. He dealt in turn with perspective in anamnesis and examination, in diagnosis, in prognosis, and in treatment, ending with some wise comments on the value of poise in a physician. Only an "I," he declared, distinguishes poise from pose, but it is a capital "I," for while the poseur is an egotist, the man with poise is usually a philosopher and often an altruist. Dr Young had but little praise for the physician who concentrates at once on the establishment of what appears to be an obvious diagnosis, neglecting the routine review of all the systems that may reveal an essential if unexpected feature. Specimens, including human ones, are best surveyed under the low power of the microscope to get a general impression, before using the high power to focus details and refinements. In diagnosis also it is essential to remember the variations in interpretation of observed data. Too often an attempt is made to fit subsequent developments to the original diagnosis, even if they seem to contradict it, instead of starting again, regarding the problem as a fresh one, and looking at it from a different standpoint. A building situated half-way up a hill looks very different when seen from above and from below, everything depends on the point of view. A double or composite diagnosis in a difficult case is always suspect—like a picture with two horizons it is usually out of drawing.

In Dr Young's experience, physicians with great experience of post mortem work rarely make "tall" diagnoses. Knowledge of the distribution of the effects of disease tends to increase clinical acumen and the modern tendency in aspirants to hospital posts to escape a period of apprenticeship in routine post-mortem work is, he finds, to be deplored. Progress depends upon many factors, some capable of statistical expression, others almost imponderable. The individual experience of the practitioner is liable to influence his opinion more than any numerical statement of the probabilities based on figures. That it is wise to remain hopeful even if the outlook is grave, and if possible to infuse that hopefulness into the patient and those around him, is a lesson which Dr Young learnt from his seniors, notably Dr G F Still and Sir James Goodhart. Thus Dr Young has confirmed for himself, and passes on the knowledge with conviction. Even when faced with an obviously lethal disease, for example, malignant disease of the bronchus or mediastinum recognised at a time when eradication or even prolonged arrest is improbable, he has been impressed with the fact that the patient rarely asked a direct question. He

suspects his fate but does not want to have his suspicions confirmed.

Among the orator's sagacious precepts the following are noteworthy. The reminder that there are fashions in treatment is timely, the three "good remedies out of fashion" (antimony, apomorphine, and aconite) quoted by Dr Young, using only the first letter of the alphabet, suggest that the list might reach formidable dimensions before one reached the last. In the choice of new remedies he noted the danger of mistaking enthusiasm for experience, a danger to which the specialist without general knowledge is peculiarly liable. It is still true that they that are sick need a physician, that is, one person in charge of them even though he calls in specialised help in diagnosis and treatment where necessary. In the medical curriculum the specialised teaching and examination now in vogue in all departments needs overhauling and close scrutiny with a view to simplification. The paradox, that whereas the doctor as an individual is trusted, the medical profession as a whole is not in great favour, is attributed by Dr Young partly at least to our traditional refusal to advertise, and is to this extent irremediable without the loss of something far more valuable than popularity. In time the public may learn to understand that it is for their protection rather than for the physician's that the code of reticence has been developed.

SURGERY IN OLD AGE

THE ageing of the population, consequent upon a declining birth rate and an increasing expectation of life, will inevitably have its effect in many economic and social aspects of life. Not least will be its reactions on the practice of medicine. Obstetricians and paediatricians must be increasingly affected by the reduction in the number of births and of children, the physicians may expect an increase in the incidence of the degenerative diseases, of cancer and of diabetes, and the surgeons a general increase in the demands made upon them, though probably not equally distributed among the various surgical specialties. There is a popular belief that advanced age is a strong argument against operative treatment, and if in the future an increasing proportion of old people is to be the material upon which the surgeon must work it is clearly important to know how far there is justification for that belief. Starting from these tenets, Dr Barney Brooks, of the department of surgery in the Vanderbilt University School of Medicine, Nashville, Tennessee, has made a study of the results of operations performed in that hospital during 1926 to 1935 on 287 patients over 70 years of age.¹ All of these patients except two had been traced until the date of death or to 1936. The results he reaches are interesting. Of 172 operations carried out at ages 70-74 years, 17, or 9.9 per cent, resulted in death in hospital, of 84 carried out at ages 75-79 there were 13 such deaths, or 15.4 per cent, and of 37 at ages 80 and over there were 6 deaths, or 16.3 per cent. Surgical diseases in these high age-groups are clearly associated with a relatively high fatality, but from the protocols of the conditions and causes of death in the patients who succumbed, which are given in detail, Brooks concludes that deaths which could be reasonably attributed to the operative treatment are remarkably infrequent. In other words, increasing the proportion of patients in the higher age groups would undoubtedly increase the

¹ Ann Surg April 1937 p 451

hospital mortality rate but should not increase the hazard of operative treatment. Further evidence is afforded by those groups of patients in which operation was undertaken solely for the relief of some distressing symptom which presumably would not necessarily decrease life expectancy—i.e. reducible hernia, cataract, tic douloureux, gall bladder disease without gangrene or perforation and benign abnormalities of the rectum. There were 90 such cases with only one death from coronary occlusion on the seventh day after operation. Most hospital deaths fell in the *genito-urinary* and abdominal operative groups, the results with the latter being the most discouraging though none of the deaths could be directly attributed to the operation. One death has a particular bearing on the subject of the paper. The patient was first seen in 1925 with gall bladder disease but because of age, hypertension and cessation of symptoms operation was not advised. The attacks recurred until 1927 when operation was unavoidable but the gall bladder was then found ruptured into the duodenum and the patient died. Given a proper technique for handling sick old people—an atmosphere of optimism, precautions against exposure to acute respiratory infection and pre-operative treatment for existing disease of the heart and kidneys—Brooks finds no strong argument against operations in old age.

THE ROCKEFELLER FOUNDATION

We have recently been reminded of the benefactions of the Rockefeller Foundation by a resumption of their policy of making travelling fellowships available for medical men and women in this country on the recommendation of the Medical Research Council. Since 1915 a sum of nearly four million pounds has been spent on fellowships in various subjects all over the world. In a review for 1936 Mr Raymond B. Fosdick, the president of the Foundation, makes it clear that fellowships valuable though they are, form but a small part of its activities. The Foundation which has been in existence since 1913 has for its aim the promotion of the well-being of mankind throughout the world and in support of this ambitious programme it has an annual income of some £2,300,000. This vast sum is expended in financing research about two thirds being spent in the U.S.A. and the remainder in all parts of the world. The subjects chosen are those which in the opinion of the trustees are likely to be of benefit to mankind as a whole and include investigations into problems of public health, medicine, natural science, the social sciences and the humanities. In general the Foundation acts by financing existing institutions but in the realm of public health it undertakes research on its own account, appointing both laboratory and field workers and concentrating its attentions on those non-preventable diseases which offer reasonable prospects of being made preventable. In 1936 investigations were in progress in the U.S.A. and some 41 other countries into yellow fever, malaria, yaws, schistosomiasis, rabies, influenza and the common cold. In medicine the Foundation's workers are mainly engaged on the problems of mental hygiene as being, says Mr Fosdick, the most backward the most needed and potentially the most fruitful field in medicine to-day. Some £339,000 was expended in this direction in 1936 including grants to the Calton Laboratory and the Maudsley Hospital in London. Mr Fosdick also remarks and one may well agree with him that if a foundation is looking for immediate results the field of mental hygiene is not the one to enter. The

natural sciences are represented in the Foundation's programme by experimental biology. For research especially in genetics, endocrinology and on the enzymes grants of £285,000 were made in 1936. The social sciences and the humanities which receive a very small share of the world's expenditure for research in general received grants of £207,000. Since 1933 the Foundation has taken under its wing 151 scholars dismissed for political reasons from their posts in Germany and has contributed £110,000 towards the salaries of these unfortunates who have found employment elsewhere.

FAT EMBOLISM

The fat of the body exists as an emulsion of very fine particles in the plasma and as deposits of coarser substance in subcutaneous tissue around the kidney and in the marrow. It is theoretically at least possible for trauma to release the depot fat from its encapsulation and lead to its absorption into the lumen of damaged blood vessels (veins). It has been considered likely that the veins of the Haystack systems being held patent by their bony surroundings, are particularly suited to injection with fat emboli. There are certain practical difficulties in accepting this explanation. The first is that for fat embolism to occur it is not essential that the bone should be broken. Manipulation of old contracted rheumatoid joints has been followed by death and autopsy has shown extensive pulmonary fat emboli. Even in the cases—much the most numerous—in which there is a fracture the severity of the lesion bears no relation to the production of the condition. The only fact about fat embolism that seems to be well established is that in its severe form it is always the result of trauma received before death. This conclusion was reached by Vance in 1931¹ as the result of an investigation of 246 autopsies. A slight degree of fat embolism may be present in non-traumatic cases but is probably not of clinical importance. It is as a sequel to fractures of the long bones that most cases of fatal embolism have been recorded and the natural assumption has been that the emboli are derived from the fat of the marrow. Watson² records a fatal case which occurred in conjunction with a serious injury—a compound fracture of the tibia—that required an emergency operation; there was comparatively little comminution of the bone. Other cases have been reported following simple fractures. Another difficulty in accepting the bone marrow as the source of the fat is that the amount of fat available in the medullary cavity of a long bone probably is insufficient to cause any serious degree of fat embolism. The mechanism of the absorption of the fat—whether by suction into the veins or by pressure from the congested tissue—is also a matter of debate.

Watson notes that the anaesthetic was not an ether one and that a considerable quantity of ether was administered; he suggests the possibility that the ether may dissolve the fat of the blood plasma which may then be precipitated by evaporation of the ether in the lungs. A further suggestion made is that the products of tissue destruction circulating in the blood may break up the fat present in the plasma, a very finely divided suspension and cause it to form particles large enough to block the capillaries. However, formed the fat emboli seem to pass first to the venous thence to the right side of the heart and so to the pulmonary circulation. Across the fat to

the systemic circulation is more difficult to explain. It may traverse a patent foramen ovale, or it may actually pass the barrier of the lung capillaries.

Two main clinical types of case are recognised in the pulmonary type the first symptom may be precordial pain, or a feeling of constriction round the chest, a cough develops, the sputum being often streaked with blood, and moist râles are heard. Occasionally the progress is very rapid, with acute œdema of the lungs, more often it is gradual and at first broncho pneumonia may be diagnosed. The cerebral type of embolism tends to mimic delirium tremens. Death is by coma. Certain organs such as the kidney seem to be unaffected by the fat in the capillaries, in the brain the grey matter is not seriously affected, but hæmorrhages are found in the white matter, with areas of necrosis and of inflammatory reaction. Fat appears in the sputum and in the urine. Pyrexia is usual. The symptoms occur early—i.e., within two or three days of the accident or manipulation. In Watson's case pulmonary and cerebral symptoms were combined. The first symptom was cough and "rusty" sputum, precordial pain followed, and twelve hours later the patient was comatose. Apart from avoidance of ether anaesthesia no very useful suggestions have been advanced for prevention of fat embolism. Once the condition has developed there is no generally accepted method of treatment, though various measures have been recommended.³ The condition is not necessarily fatal.

OXFORD MEDICAL GRADUATES AND THE UNIVERSITY APPEAL

At a meeting of Oxford medical graduates recently held in London to consider how they might best assist the Oxford University appeal, the opinion was expressed that many medical graduates would like to be associated in any contribution which they might make towards the appeal. It has therefore been arranged that a special fund will be opened to include the contributions from all medical graduates who may so desire it, the names of individuals being of course retained. It is felt that, in this way, the medical graduates of Oxford will be able more adequately to express their gratitude to their University and their desire to come to her assistance. Sir Farquhar Buzzard, president of the Oxford Graduates' Medical Club, writes in the following words of such a combined effort on the part of Oxford medical graduates—

'So long as the university was devoted in the main to the study of the humanities she was sufficiently well endowed to supply the books and the teachers necessary for these subjects, but during the last 70 years she has been obliged, in order to keep pace with modern developments to spend more and more money on education and research in scientific and sociological branches of learning with the result that she has now found herself unequal to the consequent financial burden. We medical graduates recognise perhaps better than others, how inevitable these expenses are if any institution is determined to fulfil its obligations in contributing to the advance of knowledge and in keeping its place among its rivals. As undergraduates we were apt perhaps, only to regard our colleges as our creditors as graduates we cannot forget what we owe to our university for affording us the opportunity of sitting at the feet of men like Henry Acland, Burdon Sanderson, Arthur Thomson, Francis Gotch, Georges Dreyer, William Osler, and Charles Sherrington—to mention only a few of those to whom we must always remain deeply indebted. Now is our opportunity to show that we are not forgetful of what our old university

did for us in our younger days and to give every assistance in our power to continue her great work for those who are succeeding us. Lord Nuffield, with no such obligations as ours, has endowed with unrivalled generosity a new school of medical research, and, recognising that this must increase rather than decrease the university's financial responsibilities, has already given £100,000 in response to her public appeal for money. The least we can do is follow this generous and far-sighted example to the best of our abilities and resources."

Sir Farquhar backs his views in practical manner by an offer to start the combined effort of the Oxford medical graduates with a donation of £50.

POST-MORTEM FINDINGS IN KENYA

A VALUABLE pioneer effort has been made by F. W. Vint¹ in summarising the findings in 1000 consecutive post mortems on bodies of natives of Nairobi, Kenya Colony. Pneumonia was found to be the most frequent cause of death, accounting for 298 out of the 1000. The right lung was attacked most commonly, usually the upper lobe. Only 6 of these patients were under ten years old. Tuberculosis was the next in order of frequency, the lungs being affected in 94 per cent of the 132 cases. A hundred deaths were ascribed to septicæmia and toxæmia. Only a few (26) deaths were due to malignant disease, primary cancer of the liver being rather frequent (8). Spleens were found to be large and fibrotic, whether the cause of death was malaria or not. The interesting conclusion reached by the author—namely, that infective disease tends to be septicæmic among the natives owing to blockage of the reticulo endothelial system and diminished kidney function—would seem to demand further experimental and histological evidence, his article should stimulate work on this important subject.

TARSAL SCAPHOIDITIS

Smets² draws a distinction between Köhler's disease proper and Köhler's disease with complications, the distinction being that only those cases that are complicated give rise to symptoms. His contention is that the radiographic appearances characteristic of Köhler's disease are in fact variations of normal ossification. The condition shows a strong familial tendency and has been observed in uniovular twins, thus among triplets the uniovular pair were affected while the other escaped. The case is quoted of a doctor whose son had Köhler's disease with symptoms and whose daughter on radiography proved to have similar changes without symptoms. Many cases have been discovered accidentally during routine examination of the foot for other causes—such as a search for foreign bodies, or a fracture—and Smets emphasises once more the fact that at least 30 per cent of cases are bilateral, though the condition may be painful only on one side. Furthermore, he draws attention to the frequent association of Köhler's disease with identical changes in the patella. While not denying that an infective process such as tuberculosis may give rise to similar appearances, Smets mentions one or two interesting cases in which a tuberculous scaphoid on one side, confirmed by the formation of a cold abscess, with an X ray appearance suggestive of Köhler's disease, was associated with typical changes, without symptoms in the other foot. Here it is possible, he suggests, that the tuberculous disease was an added infection. He discards trauma entirely as an important cause, but

³ Clark, G. Norman (1933) *Lancet*, 2, 77

¹ *E Afr med J* February 1937 p. 1.
² Smets, W. (1936) *J Chir Brux* 7, 377

suggests that the scaphoid going through this variation of normal ossification may perhaps be more vulnerable at a certain stage and therefore more susceptible to the influences of minor traumata; hence the symptoms.

THE CAPITATION FEE

THE Panel Conference having last year declared that £8 is too small a capitation fee for insured persons and the Minister having said he thinks it may well be too much arrangements have now been made for arbitration. The arbitrators constituted as a court of inquiry are Lord Amulree (chairman), Mr Thomas Howorth and Mr D. H. Robertson with Mr E. H. Phillips of the Ministry of Health as secretary. Their task is to advise what if any alteration should be made next January in the capitation fee having regard to any changes which may have taken place since 1924 in the cost of living the working expenses of practice the number and nature of the services rendered by insurance practitioners to their insured patients and other relevant factors. The inquiry is to proceed on the assumption that employed persons under 16 years of age will by that time be entitled to medical benefit and the arbitrators' findings should help to resolve the conflict of opinion that has arisen from the Minister's belief that a substantially lower fee should be paid for children than for adults.

MENINGOCOCCAL MENINGITIS TREATED WITH SULPHANILAMIDE

SULPHANILAMIDE as *p*-aminobenzenesulphonamide is conveniently called has been proved lethal to meningococci¹ and account on its use in cerebro-spinal fever are eagerly awaited. A small series of cases now reported from Baltimore is encouraging so far as its good. Schwentker, Gelman and Long² have treated 10 patients with meningitis and 1 with meningococcal septicaemia—the series being to all intents and purposes consecutive—and are able to record recovery in all but 1 of them. They used a physiological solution of sodium chloride containing 0.8 per cent of sulphanimide and they gave it by intraspinal and subcutaneous injection. They began by withdrawing cerebro-spinal fluid and replacing it with the sulphanimide solution the amount injected varying from 10 to 30 c.c. and usually being 5 to 10 c.c. less than the amount of fluid withdrawn. A larger quantity of the solution was then given subcutaneously they injected about 100 c.c. for each 40 lb (18 kg.) of body weight. Both intraspinal and subcutaneous injections were repeated every twelve hours for the first two days and once daily thereafter until definite improvement was evident. Sometimes the cell count of the cerebro-spinal fluid fell rapidly and progressively; sometimes it remained high for a few days and descended precipitately. In no case could organisms be found in the C.S.F. more than three days after treatment started. No untoward effects were noted the subcutaneous injection gave no more reaction than would be expected with normal saline and there were none of the signs of systemic reaction sometimes reported after sulphanimide such as rashes methaemoglobinuria or sulphamoglobinuria.³ Schwentker and his colleagues are rightly cautious in their con-

clusions but in their 11 cases they found the therapeutic response quite comparable to that which usually follows treatment with specific antiserum and they point out that sulphanimide has the substantial advantage over serum that it does not cause irritation like a foreign protein.

RISKS OF ENDOTRACHEAL ANÆSTHESIA AND OF EXPLOSIONS

A CONTROVERSY has been going on in the last two numbers of the *British Journal of Anaesthesia* over the possible dangers of nasal endotracheal methods. Dr Massey Dawkins in January asserted that bacteria lie within the external nares whence they are normally removed by ciliary action. The nasal catheter he thinks may carry these organisms directly to the trachea where they may not be effectively dealt with. He quotes two fatal cases of broncho-pneumonia following endotracheal anaesthesia which he believes illustrate and support his contention and he also produces statistical evidence. His opinion is that administration of an endotracheal anaesthetic for every case is becoming too common though he does not deny that the method is certain easily controllable and admirably suited to the needs of the surgeon and of the anaesthetist. The edgels in defence of nasal endotracheal methods were taken up in the April number and wielded with vigour. Dr Ivan Magill who was the originator of this method and has employed it since 1910 has not yet met an instance of pulmonary complication that could justly be attributed to it. He holds that any bacteria present in the nose are probably already present in the trachea too. He agrees with Dr Dawkins that indiscriminate use of the endotracheal method by all and sundry whether indicated or not, is to be deprecated. Mr W. A. Mill suggests that the best way to avoid lung complications is to avoid operating until some time has elapsed after any acute infection of the upper respiratory tract. Cocainisation of the nares the use of a small tube an anaesthesia deep enough for insertion of the tube without spasm of the cords and lubrication of the tube are features of the technique which other writers to the journal regard as important.

Another paper in the April number by Mr I. H. Coste F.R.C. deals with the cognate question of fire and explosion in operating theatres. It is a valuable contribution because other investigators have usually given primary consideration to the source of the spark or flame which starts an explosion. Mr Coste examining the chemical aspect has experimented on the explosibility and inflammability of a number of the commonly employed inhalation anaesthetics. He gives numerous details and as regards ether draws the important practical conclusion that explosions due to dangerous concentrations of ether in the air of an operating theatre are most unlikely if the possible source of ignition is a foot or more above the floor level.

CEREBRO SPINAL RHINORRHOEA

CEREBRO SPINAL rhinorrhoea is rare in a person condition since it carries with it the danger of meningitis. Diagnosis is easy if the point is not forgotten; profuse flow or free dripping of a clear fluid which does not stain on the handkerchief is a characteristic sign confirmed when chemical examination of the fluid shows absence of albumin and mucus and the presence of glucose. The cases fall into three groups: (1) those due to injury (2) those

¹ Huttel, G. A. H. Gray, W. H. and St. Johnston, D. (1936) *Lancet*, i, 1, 80. Brown, H. and J. H. and 1937, p. 16.

² Schwentker, F. J., Gelman, H. and Long, J. H. *J. Amer. med. Ass.* April 24th 1937, p. 140.

³ See paper by Talon and Eaton on p. 119 of our present issue.

which follow operation on the frontal sinuses or ethmoid region, and (3) those which occur without previous traumatism. On May 7th, in a communication to the laryngological section of the Royal Society of Medicine, Prof. Hugh Cairns described eight cases illustrating these various groups. Two were the result of airplane crashes, where the face had come into violent contact with the instrument board, causing fracture of both walls of the frontal sinus. Mr Cairns suggests that such accidents may become increasingly frequent. In both subjects rhinorrhœa ceased after a few days and recovery followed. In these cases early operation is contra-indicated, for severe shock is usually present as well as infected wounds of the neighbouring regions. In other cases rhinorrhœa may not appear for several weeks, if it persists, there is considerable risk of meningitis through infection from the nose, which may occur at any time as the result of a cold. It is therefore wise to operate, expose the floor of the anterior cranial fossa, and close the rent in the dura by suture or by a fascia lata graft.

If a flow of cerebro spinal fluid is seen during an intranasal operation on the ethmoidal region, it means that the dura mater, which is particularly thin and adherent here, has been torn. The danger of fatal meningitis is extremely grave, and the safest course is to open the anterior fossa at once and repair the wound. Mr W. M. Mollison pointed out, in the ensuing discussion, that injury to the dura during external operations on the frontal sinus and ethmoids is less liable than injury during intranasal operations to be followed by meningitis.

Cerebro spinal rhinorrhœa in the absence of traumatism is sometimes associated with hydrocephalus or with cerebral tumour, and may cease after removal of the latter. Sometimes it is more truly spontaneous, and is then probably due to congenital defect in the region of the cribriform plate. St. Clair Thomson first called attention to this condition in 1899, when he had seen three cases, all ending fatally, and remarked that the condition does not appear to be amenable to any treatment.¹ In view of the serious risk of meningitis, probably the safest course is to expose the anterior fossa and close the gap with a graft, especially where a deficiency in the bone is shown by X-ray examination.

ROYAL SOCIETY OF MEDICINE

ON May 10th the Royal Society of Medicine gave a reception at the Society's house to celebrate the Coronation and to entertain medical men and their wives from overseas. The guests were received by the president, Sir John Parsons, F.R.S., and Lady Parsons in the library. A film show in the Barnes Hall was preceded by a short speech in which the president extended the hospitality of the Society to all visitors and welcomed guests. Among the official guests were Mr James Davies, Commissioner for Newfoundland, Sir Thomas Barlow, president of the Royal Medical Benevolent Fund, Sir Edward Mellanby, secretary of the Medical Research Council, and the presidents of many of the sister medical societies which have their headquarters in London, there were also visitors from Australia, New Zealand, Canada, Africa, India, Malta, New York, Straits Settlements, Palestine, and Greece. By the courtesy of the General Post Office two excellent films were shown. The first, "Weather Forecast," demonstrates how from meteorological data collected from all over

Europe a gale is forecast, one follows the "gale warning" through all the departments concerned and finally sees in outdoor scenes the gale rise and pass away. In the second, "Night Mail," are recorded the various stages of the mail as it flies north through the night on a special express, and there is an exciting moment when the mail from Holyhead nearly misses its connexion. A third film "Galatea," by Miss Lotte Reiniger, was a clever silhouette made up with pieces of paper and cardboard, the subject matter of which had been freely adapted from the classics.

An exhibition of historical interest followed, consisting of tableaux depicting medieval alchemist shops, and the progress of medical science through the centuries. The tableaux were lent by the Wellcome Historical Medical Museum as were a collection of figures of the patron saints of medicine, including Saint Sebastian, the patron saint of undertakers. Altogether a successful and entertaining evening.

THE HONOURS

THE Coronation honours list is for the Empire as well as for this country, and it brings recognition to many whose work is done in out of the way places. Medicine in England gains another able exponent in the House of Lords in Dr Christopher Addison, whose long parliamentary service and tenure of several ministries are fittingly recognised by a peerage. Sir Cuthbert Wallace receives a baronetcy, Dr Edward Mellanby is created K.C.B., Dr G. F. Still and Sir John Atkins become knights of the Royal Victorian Order, and Dr A. F. Hurst, Prof. Beckwith Whitehouse, and Dr A. E. Horn are among the new knights bachelor. To these and the other members of the profession named on p. 1204 we offer warm congratulations. In addition, there are many associated with medical work whose decorations we are also glad to note. Mr S. P. Vivian, the Registrar General, receives a knighthood. Mrs. Ellen Pinsent, late senior commissioner of the Board of Control, is made a dame of the Order of the British Empire, and the nurses honoured include the matrons of St. Bartholomew's and King's College Hospitals, Miss Helen Dey and Miss M. A. Wilcox, who become officers in the same Order.

THE next session of the General Medical Council will open on Tuesday, May 25th, at 2 P.M., when Sir Norman Walker, the president, will deliver an address.

ON March 6th we reviewed the report of the Select Committee on Medicine Stamp Duties which proposed the taxation of a large range of preparations recommended or advertised as curative or preventive of illness. This report is now published by H.M. Stationery Office with the minutes of evidence and an index. The price is 7s. 6d.

THE centenary celebrations of the Liverpool Medical Institution will be held on May 30th and 31st and June 1st, when honorary memberships will be conferred on Sir Cuthbert Wallace, Sir Norman Walker, Sir Farquhar Buzzard, Sir Ewen Maclean, Prof. W. Fletcher Shaw, Sir James Barr, Mr Thurstan Holland, and Mr Frank Paul. Prof. R. E. Kelly will deliver a presidential address on surgery a hundred years ago. During the meeting the Hugh Owen Thomas and Robert Jones memorial library of orthopedic surgery will be opened and afterwards Mr W. Rowley Bristow will give the Hugh Owen Thomas memorial lecture.

SPECIAL ARTICLES

EMPIRE CONFERENCE ON THE CARE AND AFTER CARE OF TUBERCULOSIS

(Continued from p. 1181)

Lord HORDER and Lord ALLEN OF HURTWOOD presided over the sessions of this congress on May 4th. Lord Horder said that despite the advance made against tuberculosis the mortality remained far too high. Lord Allen referring to the Papworth experiment said it interested him because of the humane-ness and sympathy it brought into administration. One of the major needs of democracy he thought was emphasis upon the humane.

TUBERCULOSIS IN THE BRITISH ISLES

Various papers were read describing work being done in the home countries.

Dr D. A. POWELL (principal medical officer Welsh National Memorial Association) said that the fall in the tuberculosis death rate in Wales though substantial had not been as great as in England. This fact must be connected with the national characteristics of the Welsh such as the intense conservatism of their social habits, the closeness and tenacity of their family relationships and their fatalistic outlook. In Wales broadly speaking families were either free from the disease or were riddled with it and it ran in families because of excessive opportunities of infection rather than because of hereditary lack of resistance. So closely woven were town and country that in dealing with a chronic infectious disease such as tuberculosis Wales had to be looked on as a unit. The main services undertaken by the Association included: (1) the provision of institutional treatment in sanatoriums and hospitals; (2) the provision of dispensary or out-patient treatment for which purpose Wales was divided into 14 areas which disregarded when necessary local government administrative boundaries; (3) the establishment of clinics for the continued treatment and supervision of surgical cases; (4) the establishment of an educational department; (5) after care; and (6) the maintenance of a central research laboratory. The liaison between the institutional and the dispensary sides was extremely close—administratively through the head office and the principal medical officer and clinically through interchangeability of staff, the appointment of tuberculosis officers as visiting physicians, the appointment of medical officers of surgical institutions as officers in charge of the surgical after care clinics, the carrying out of joint investigations such as that into coal miners' lungs and the holding of periodic staff conferences. The Welsh National Memorial Association was unique in that it combined the advantages natural to a voluntary organisation with those in operable from a State and rate-aided service.

Dr ERIC WATT (Department of Health for Scotland) said that in Scotland there was now roughly 1 bed per 1000 of the population but even now there was often a waiting list. A great deal had been learnt about the problem of tuberculosis since the inauguration of official schemes. It was important to preserve a critical outlook upon all activities engaged in the campaign.

The MARCHELONNE ST. ANTHONY gave an account of the formation of the Women's National Health Association in Ireland in 1907 and the organisation of a travelling anti-tuberculosis exhibition which

resulted in the establishment of a network of local branches of the association and a steady decrease in the tuberculosis death rate. The rate recorded for 1936 was the lowest yet reached (1.13 per 1000) and was approximately 59 per cent less than that for 1904. With a government grant of £25,000 two sanatoriums were established near Dublin and Enniskillen. It was not until 1929 however that they were able to make a start by establishing the Peamont Industries and adopting the Papworth plan of working for the establishment of a village settlement. Lady Aberdeen spoke of the remarkable change of atmosphere which had been brought about during these seven years—a change that had transformed the work.

Dr G. LIESANT COX (Lancashire County Council) described some of the measures for prevention and treatment that have been adopted in Lancashire. If treatment was over-emphasised, he said they would have a poor scheme and faulty control. The importance of prevention was seen when it was realised that some 60 per cent of adult pulmonary tuberculosis cases died within five years of coming under notice. The Lancashire scheme was built up on the principle of finding, isolating, educating and treating the adult positive case. Finding had to be done by notification and by active co-operation between family doctor and whole-time municipal or State doctor. Isolation was carried out by keeping infective patients in hospital as long as they would stay. In Lancashire they had 680 beds, which was just enough for their 8.5 pulmonary deaths. Education was carried on by teaching in schools (incidentally all schools ought to be open-air schools) and teaching by the tuberculosis medical service in hospitals, sanatoriums and homes of the patients. Treatment included all modern medical and surgical methods. It was always free and Dr Cox considered that this policy had helped to give them their reduction in incidence and fatality. Schemes for the care and after-care of the patient were an important part of treatment and were most highly developed in the village settlement.

THE HOSPITAL AND THE VILLAGE SETTLEMENT

Dr L. S. T. BURRELL said that when tuberculosis was recognised either as a primary infection or as a reinfection the object of treatment was to make the lesion heal without spreading and it was in this stage that the hospital was valuable. It was impossible to over-estimate the value of an initial period of rest in cases of pulmonary tuberculosis. When the activity of the disease was arrested the function of the sanatorium would come into play. Secondly when the patient was so ill that he could do little or nothing for himself he should be in hospital not only for his own sake but also to prevent infection of others. The third great function of the hospital was as a centre for diagnosis. At the Brompton Hospital a large number of patients came mainly for this purpose and were subsequently drafted to the appropriate institution.

Dr I. B. McDONNELL (Preston Hall) spoke on the re-settlement of the tuberculosis ex-service man. From their early experience of the Preston Hall scheme they had learnt that for the success of any village settlement medical principles must take precedence over every other factor in the life of the community. Another important lesson they had learnt was that the leader of the various departments should be recruited as far as possible from the

tuberculous population The principles employed at Preston Hall were substantially the same as at Papworth. They now had accommodation for 300 patients suffering from pulmonary tuberculosis, and treatment of every kind was available. With regard to the purely industrial side, if the products were good and the price was right, there was no reason why trading in the open market should not be as successful in a village settlement as in any outside organisation. A recent Ministry of Health report (1932) had pointed out that a subsidy to a patient in a village settlement was more economic than allowing the patient and his family to be supported, entirely unemployed, from the public assistance funds. He had often wondered what the country would be saved financially by acting on a large scale on this dictum.

SURGICAL TUBERCULOSIS

Sir HENRY GAUVAIN said that in the vast proportion of cases conservative surgical tuberculosis treatment was the treatment of choice. Occasionally radical treatment was preferable, as for example in most cases of tuberculous disease of the knee joint in adults, where excision was very often indicated, both because duration of treatment was thereby shortened and danger of recurrence largely avoided, and also because the resulting disability was comparatively trifling, and indeed was often less than if protracted conservative treatment were employed. It might also be desirable for small tuberculous foci which could be readily and completely removed. In tuberculous disease of the spine and hip there was much controversy as to when fixation operations should be undertaken. In his own experience these operations were not advisable as a rule during active and progressive disease, especially in the presence of deformity, since deformity could nearly always be reduced or corrected during treatment. The treatment of tuberculous glands of the neck varied with the type of case, but usually a preliminary period of conservative treatment was useful, after which if necessary any hard glands remaining which were unlikely to be absorbed should be carefully excised. In tuberculous of the abdominal glands also conservative treatment was always the method of choice and operations avoided whenever possible. The Triboulet test he thought was sometimes a useful guide to the condition of the large intestine.

EXPERIENCES IN THE DOMINIONS

Dr R. J. COLLINS (Canadian Tuberculosis Association) said that in Canada they had no centralised—i.e., national—department of health. Each province built up its own schemes, agreeing in objectives but differing in methods. In his own province of New Brunswick special emphasis was being laid on better housing and diet, the establishment of numerous clinics, and adequate after care. Very little constructive work had so far been done in respect of housing, otherwise the advances made paralleled those in England. The introduction of travelling clinics had done a great deal. In 1928 survey work—group examinations—had been begun with the entry classes in the universities, and this had gone on to other survey groups. These plans were duplicated more or less throughout Canada. They had an average in Canada of 1½ beds per tuberculosis death. Saskatchewan had 2 beds per death, but the maritime provinces had less financial means. With the object of shortening hospitalisation and rendering the sputum negative there had been a great increase in artificial pneumothorax treatment and thoracoplasty, and at the present time some 20 to

50 per cent of the sanatorium population received some form of collapse therapy. There were 20 centres in New Brunswick alone for A.P. refills. The employment of ex-patients was very valuable. Occupational therapy the speaker thought rendered little service towards future employment. Vocational training could be made more effective if there was more diversity of subjects, and it should be supplemented by some scheme for the subsequent placing of the patient in sheltered employment. After care in Canada was a problem affecting some 10 per cent of the discharged patients.

Miss GLORIA LANGMAID (Canadian Association of Occupational Therapy) said that occupational therapy was now part of the equipment of every up-to-date sanatorium in Canada. It assisted young patients to adjust themselves to their new conditions, and aroused their interest in new directions.

Mr D. M. DEANE described the work of the Tubercular Soldiers' Aid Society, Adelaide.

Dr A. J. COLLINS (Commonwealth of Australia) said that notification of tuberculosis was compulsory in Australia, but the State was powerless if a man declared he could not afford to give up his work to undergo treatment. Unless financial assistance was available for their dependants, a certain proportion of tuberculous patients would not avail themselves of the necessary institutional provision. The public health officer should be empowered to insist on adequate treatment in every case.

At a subsequent session the Hon. FRANCIS GARA (Minister of Health, Tasmania) said that the principal difficulties in Tasmania lay in organisation, transport, and public apathy. Sometimes they had to take their people as far as 200 miles away from their homes and to put them in the central institution set apart for special treatment. The patient often rebelled at being transported so far, with the result that they had been dealing with a later stage of tuberculosis than could be found in centres where clinics could be readily located. The Government was about to establish a full time free medical service for people living in the remoter portions of the State. The medical officers were to be part of a central medical scheme run in conjunction with Tasmania's public hospitals, and were to be given frequent opportunities for refresher courses in the hospitals. A central sanatorium along modern lines was also in process of development. Where centres of population permitted, it was intended to adopt the British method of tuberculosis clinics, classification and ambulatory treatment generally. More ambulance units were to be installed to facilitate transport, health talks by radio were to be given, and elementary instruction in hygiene provided by the State schools. The speaker concluded by referring to the fundamental importance of guaranteeing to the public a pure milk supply.

INDIGENOUS RACES

Viscount GOSCHEN took the chair at the fifth session. He emphasised the importance of a free exchange of information.

Dr CHARLES WILCOCKS (Tanganyika Territory) gave the results of a five year investigation of tuberculosis conducted by him in Tanganyika inhabited by some 5,000,000 natives, mainly of Bantu origin. For the tuberculin survey the Mantoux technique was used throughout, supplemented by stethoscopic examination, collection of sputum if desired, and an X-ray examination of suspected cases. In 1936 such examinations 114 cases of definite tuberculosis were found, giving a crude rate of 11.5 per 1000.

In every place half or more of the adult population were positive to tuberculin, the rates for children being lower. Of X ray films of 100 unselected contacts 16 per cent showed definite tuberculous infiltration of the lungs. In a larger series of contacts who were tuberculin tested 83 per cent of all ages were positive, of whom some were contacts of non-pulmonary cases. The results of the survey suggested that continuous exposure to exogenous reinfection tended to produce first sensitivity then hyper-sensitivity and finally disease and if the highly allergic state was harmful rather than protective then the process might be a continuous one. The dominating factor was contact. The prognosis in native tuberculosis cases was usually bad. This might be due to late diagnosis, poor living conditions and diet or possibly to a racial predisposition to the disease perhaps increased by concurrent diseases and with better conditions and treatment an improvement might be looked for. The resistance shown by the infected natives proved that under most circumstances they could control their infection. It might take very little to increase that capacity for control so that a repetition of the experience of the North American Indians might be avoided.

Major General Sir CUTHBERT SPRAYSON (Indian Medical Service) said that the Indian population as a whole was more susceptible to tuberculosis than the population of Great Britain. There were also special difficulties inherent in the purland system and the early marriage of girls, while another peculiarity of tuberculosis in India was the large proportion of cases of primary abdominal tuberculosis. Infection from the bovine tubercle bacillus however was believed to be rare. The dispensary system of tuberculosis control in this country presupposed existing hospital or sanatorium accommodation for all the cases the dispensary might send but in India such accommodation did not exist. There was an urgent need for increased hospital accommodation by which the most essential link in the chain of case disposal would be achieved. There was also room for a tuberculosis settlement on the lines of Papworth—i.e. an institution receiving cases of all types with its own dispensary, hospital, sanatorium and factory. No such settlement had yet been established in India but if every Indian city with a population of 100,000 or more were to start a tuberculosis settlement a few miles outside municipal limits with accommodation and arrangement for expert treatment of patients of all types and with separate quarters for the families of those fit to resume work the speaker believed that a need would be met and the public health improved. Money should be raised mainly by public subscription rather than by government aid and by many small subscriptions rather than a few large ones.

Dr F. A. BENJAMIN said that a tuberculin survey by the Union Mission Sanatorium, South India, suggested that the infection even in the villages was widespread, the disease usually being of the acute rapidly developing type. In spite of the widespread infection and severity of type there was a surprisingly small amount of tuberculous disease in the area of the tuberculin survey. The fact that the type of disease met with was almost exclusively acute exudative might be due partly to auto-inoculation brought about by undue stress or unfavourable environment during a period of relative instability in tuberculosis immunity and partly to exposure to repeated small live doses of tubercle bacilli from outside. As many as 40 per cent of the patients gave a history of direct contact with tuberculous patients. Dr Benjamin urged that further research work should be under-

taken through surveys in different areas but controlled under a single control also that efforts against tuberculosis should not be wasted in a general broadcast type of propaganda but should be concentrated and directed to reach and educate the few among whom the disease is actually found and finally that efforts should be made to detect, treat and isolate those who were a serious source of danger to others.

Mr NORMAN MACLENNAN (Department of Health, Palestine) said that a tuberculin survey had been carried out amongst all sections of the Palestine population in 1934-35; observations were also made on tuberculin sensitivity rates in school-children 5-13 years of age. It was found that the Palestine rates were considerably less than half the figures given for London and for Leeds and it was likely that the process of tuberculation would increase in the near future. The immigrant adult Jewish population was however probably already tuberculated. Factors generally admitted to be operative in promoting the incidence and spread of tuberculosis existed in a large proportion of the population. These factors were uncontrolled infection, poverty, malnutrition, over-crowding, ignorance and insanitation. As far as the nomadic Bedouin in Transjordan were concerned both individual and racial resistance appeared low and the disease was often of the galloping variety. Bovine infection apparently played a negligible rôle in the production of the disease in Palestine.

Prof S. LYLE CUMMINGS presided over the last session of the conference.

Dr BERNARD MEYER, speaking on tuberculosis in New Zealand, said that Maoris contracted tuberculosis more easily than the New Zealanders of European descent and appeared also to have a lessened resistance to the disease so that the death rate was distinctly higher. The hygienic conditions under which the Maoris lived and their reluctance to adopt the necessary European methods made their treatment very difficult. An advance had however been made by the establishment of tuberculosis clinics in various parts of the North Island and a tuberculosis scheme was being organised which was expected to bear fruit in the near future. Dr H. B. Turbott, medical officer of health at Hamilton, New Zealand, carried out in 1933 a thorough survey of a typical Maori country population and the knowledge gained resulted in the adoption of a care and after-care scheme over the same area covering about 4000 Maori population. The tuberculosis mortality in the demonstration area dropped to less than half between the years 1934 and 1936. And thus after three years' trial the scheme had proved sufficiently successful to recommend for adoption for Maoris throughout New Zealand.

Dr J. CAUCHI (Nigeria) dealt with tuberculosis in West Africa. Explaining that Nigeria had an approximate population of 20 million over an area of just under 373,000 square miles and that outside the municipal area of Lagos there were almost no qualified men in private practice—the actual available strength of the establishment in the country at any one time amounting to less than 100 medical officers—he said it was obvious that only a small minority of those suffering from disease could ever come to the notice of the medical organisation. It was then for unavoidable that their knowledge of the incidence of tuberculosis in Nigeria should be limited although the incidence was known to be high. In 1935 in the return of Government institutions tuberculous infections accounted for over 23 per cent of the total of 536 fatal cases of infection.

disease. The two main clinical groups of cases seen in Lagos were (1) those showing cavitation and surrounding fibrosis of the lungs, and (2) those showing multiple lesions of the various organs and tissues. In both groups the disease followed a steadily progressive course with little or no evidence of reparation or retrogression. It was thought possible that these two groups might be correlated to two different strains of *Bacillus tuberculosis*. If this theory was confirmed, it should have a bearing on practical methods of control. Tuberculosis had been made notifiable since last year for the whole of Nigeria, and cases were being reported from many of the hospitals. Lagos had been undergoing rapid urbanisation in recent years, and as house-building had lagged behind the increase of population over crowding had resulted, with its increased opportunities for infection. Town planning and housing improvements which were now being energetically carried out constituted sound lines of control. There was also some evidence of tuberculosis among cattle in widely scattered districts. There was thus ample material for tuberculosis research by clinician, laboratory worker, and public health officer as soon as the country could afford to add to its present much too limited staff.

The conference concluded with speeches from Dr A. D. PRINGLE, representing the Transvaal Chamber of Mines, and Dr G. M. C. POWELL, representing the medical services of Northern Rhodesia.

AN AMBULANCE IN SPAIN

LAST November we published a letter from Mr K. Sinclair Loutit describing the work of the Spanish Medical Aid Committee's ambulance unit at Grañen in Aragon. In December most of the personnel left for an area of greater activity and the following letter gives a further account of what they are doing.

"Here on the Madrid front we lead a very different sort of life. In the three months we have been here, we have established five different hospitals and treated, in round figures, 2000 wounded. Our function is that of mobile hospital to the XIV Brigade which means that we lead a very active life, often being compelled to pack up, transport, and re-establish the entire hospital in 24 hours. In the beginning we found this a well nigh impossible task, but now, with proper division of labour and systematised packing, we are beginning to look upon it as being all in the day's work. We are usually housed in large villas of fascist ownership which, with a little initiative, can be converted into excellent first-line hospitals. This is not always so, however, and in one case the choice lay between a baroque palace, the walls of which were festooned with cupids and saints chasing each other round with a fine disregard for the laws of hagiography, and a sixteenth century Alcaidia. We chose the latter because the rooms were larger and there were accessible water and some elementary sanitation. It was built round a most beautiful courtyard and among its amenities was a bar which between 4 A.M. and 7 A.M. was converted into an operating theatre—much to the surprise of some local inhabitants who dropped in for 'a quick one' at 9 o'clock. The public hall became our largest ward, every other part of the building being utilised, so that when we came to leave six weeks later, the place was wired for electric light, there was running water on the premises and the lavatories were up to normal English standards.

"We carry with us a carpenter, an electrician, and

a plumber, who in Spain are as essential as any of our personnel. They also confer a lasting benefit on any premises we occupy, thus when the line advances, the civilians reoccupying those houses find their last state better than their first.

"We usually arrive at the village that has been chosen for us—some 14 or 15 kilometres behind the firing line—in the small hours of the morning. Large convoys by day are too vulnerable to aerial attack. Our house, which has already been marked and is often enough Hobson's choice, has to be immediately prepared for the results of the dawn offensive, which will begin to arrive about 9 A.M. Three things are our first attention: (a) a working operating theatre, (b) a minimum number of beds, (c) a proper water supply. This is sufficient for the first rush and the rest can be completed in the subsequent 24 hours.

"We attempt to follow the same plan in all our hospitals. We start with a large reception room which can hold about 15 stretchers and the same number of ambulant cases. Here, as the cases arrive, a rapid sorting is performed by the reception officer and the wounded are dispatched to major or minor operating theatres, or, in cases of great shock, straight to the wards. He, too, is responsible for evacuations, dispatching those who can stand further transport farther back from the line. Here, also, any first-aid treatment is given, the pre-anæsthetic dopes, antitetanic, and anti-gas gangrenous sera, morphine, and, with the lighter cases, a very welcome cup of coffee and a cigarette. Next comes the operating theatre, or theatres. We have always found this a great problem. It is difficult to find a series of suitable and adjacent rooms to give our operating teams separate theatres. In the last two hospitals we have had to put all five tables in the one large room—this has proved an admirable arrangement and an economy in both material and staff.

"The theatre and reception room having been chosen, the rest of the house goes of necessity to wards, office, and kitchen. Our small sterilising room is in a way the most vital part of the hospital. We cannot rely on prepared dressings nor can we allow anyone else to do our sterilising, and so, for instance, every bit of gauze is cut and autoclaved on the premises. Our steriliser, an ex-R.A.M.C. orderly, kept hard at it keeping up the ever diminishing stocks.

"The whole organisation is designed on such a scale as to deal with about 120 cases daily, with 5 operating tables and 70–80 beds.

"Having settled the all important question of the hospital, the billeting officer has to house and feed some 50 personnel. Amongst our number are representatives of every European country—English predominating on the medical staff. This does not, as one might expect, result in a babel, for the war has produced its own language, a sort of trench Spanish. A little difficult for lengthy conversation with a Spaniard, but quite enough for a Czech and an Englishman to make each other understand.

"As we are so close to the line we cannot rely on uninterrupted or fixed hours of work. We have often had to work the 24 hours round and that under the difficulties entailed by air raids, failure of the light supply (here the grid system often works right up to the front line) and all the other accidents of war. A Belgian driver has now rigged up a very effective emergency lighting plant for the theatre out of salvage from car wrecks and a dynamo from a bombed garage, so now we can carry on with something better than flash lamps and candles.

For the sanitary service there is no rest. When our brigade is 'en repos,' we, although things are

naturally quieter, have a full day's routine work with medical (as opposed to surgical) patients, occasional civilian road casualties, routine inspections and inoculations. Then there is the checking up of stores from which arise those urgent appeals you receive (and we hope attend to at once) sent out by our London committee. Then the theatre staff are fully occupied in preparing dressings, manufacturing plaster bandages, repairing gloves and cleaning and adjusting instruments. During these brief rest periods each arm of the brigade tries to organise an evening's entertainment for the remainder of the service. First a musical entertainment followed by a dance—always described as a *Gran Bal*! As the women are naturally in the minority there being only eight English nurses and a few Spanish girls from the village there are no wall flowers and one sees such couples as a 6 foot Belgian regimental sergeant-major walking around with a 5 ft 4 in Polish dispatch rider. The order to move comes and back we go to some hard pressed sector.

The contrast between this and our former work on the Aragon front strikes one from every angle. At Grañen we were permanently established behind a stationary defence line. Spain was on the defensive. That line at any rate when we arrived there last August was manned by disorganised militia without unique command without concerted plan of action. All that has passed. And now eight months later we find ourselves behind a determined and disciplined army engaged in an offensive which stretches from the borders to the seas against a foreign fascist invasion. Thus *No Pasaran* has changed to *Nosotros Pasaremos*.

MEDICINE AND THE LAW

A Disputed Will

IN 1908 a Lancashire gentleman took to his bed complaining of influenza and malaise. He had a slight rise of temperature but did not appear to be seriously ill. In a few days, however, his illness took a serious turn and his doctor was summoned. The patient obviously had an acute abdominal emergency and diagnosis of a perforated typhoid ulcer was confirmed by a second opinion. He was given occasional doses of morphia—gr $\frac{1}{2}$ hypodermically—to ease his pain. In a day or two he died but a few hours before his death he was propped up in bed and signed a long will which had been prepared by his solicitor and by which he left his wife an annuity and the bulk of his fortune to his sons and their descendants. His daughter then only a few months old received only a small share of the testator's inheritance from his father. For various reasons she did not learn of the circumstances in which the will was executed until 1936. She then issued a writ against the executors alleging that the will was not properly executed because the testator when he signed it had not possessed sound mind, memory and understanding, that he did not know and approve of its contents and was delirious and comatose the day before and continued in this state with intervals of consciousness until he died, that he suffered a great deal of pain and distress, and died two hours after the execution of the will; that he gave no instructions for the will that it was not read over to him and that he could not appreciate or understand its meaning, effects, or contents, or form a rational opinion of his financial position or the claims of his family on his testamentary dispositions.

The action was heard before Mr. Justice Langton on April 22nd, 23rd and 27th. By good fortune

Dr. Walter Rigby, the testator's medical attendant and a witness of the will was able to give evidence of the circumstances. He said that the dying man's mental state was quite clear. There had been nothing to show that he knew it was his will but there was no doubt that he did know. Cross-examined he said that perforated typhoid ulcer was very rare but almost certain to cause death in two or three days; that delirium was not a common feature of the illness unless the temperature was high. Typhoid being a low fever this was not usual. The patient although not quite normal was perfectly in possession of his senses and knew quite well what he was doing. He could see and was conscious of his surroundings. He had no persistent agony or pain nor had he been delirious or comatose within the doctor's knowledge. Other evidence showed that the will had been drafted on the instructions of the testator. It has been settled law since the case of *Parker v. Felgate* 1883 8 P.D. 171 that if a person has given instructions to a solicitor to make a will and the solicitor prepares it in accordance with those instructions the testator need only be able to reflect: 'I have settled that business with my solicitor. I rely upon him as having embodied it in proper words and I accept that paper which is put before me as embodying it.' As the case was settled the court had no opportunity of hearing evidence by Sir William Wilcock and Dr. G. W. B. James on the probable effect of a perforated typhoid ulcer on the mind of a testator. The case is interesting not only because the cause of the alleged testamentary incapacity was unusual but also because although the events happened nearly thirty years ago the evidence of the medical attendant was available. Its absence would probably have handicapped the executors considerably for the onus was upon them to prove that the will had been properly executed.

REFORM OF THE CURRICULUM

(FROM OUR EDINBURGH CORRESPONDENT)

A DISCUSSION on medical education was held last week in Edinburgh under the aegis of the University Union.

Sir FRANCIS FREEMANTLE, speaking as a medical Member of Parliament, said that in establishing the General Medical Council Parliament had delegated to the profession itself the duty of maintaining standards of education and etiquette. The standards thus attained were high but the dual factors of government protection and stereotyped training had resulted in a rigidity of mind in the profession and an undue bias against innovations as was exemplified in its tardiness to acknowledge the principles of homoeopathy and osteopathy. Among changes he would recommend in the medical curriculum was more thorough instruction in the history of medicine to offer encouragement and to foster the student's pride in his profession. Teaching should be directed rather to the maintenance of perfect health than to the cure of disease and a place should be found for instruction in administration and communal medicine. He accused physicians of faulty pathology; the identification of an organism should not end the investigation of a case; the patient should be followed to his home or place of work and the prime cause which had enabled that organism to flourish should be sought and eradicated. Students should be judged in examinations not only by the marks then obtained but also by their previous record of work, intelligence and tact.

Dealing with the supervision of medical schools

by the General Medical Council, Sir Francis maintained that the Council's powers were too restricted, further that the Council, as now constituted, with members who had received their training upwards of thirty years ago, was not a suitable body to make the necessary improvements. There was but little prospect of aid from the Government in reforming the medical curriculum, and such reform must be initiated by the individual medical schools, and especially by the universities. He favoured the appointment of younger men to the General Medical Council, the addition of student representatives to boards of studies, lay representation of the health services on the General Medical Council, and the formation of a statutory Health Council under the Privy Council, which would assist the General Medical Council in the necessary reforms, and be responsible to Parliament for the co-ordination of health services.

Dr G. O. BARBER (Cambridge and St Mary's Hospital, London) spoke as a general practitioner. The student, he said, tended to regard the acquisition of a medical degree as fully and finally qualifying him to undertake the care of patients. This view was encouraged by the general public, which placed unfaltering faith in those who hold such a degree. In point of fact the possession of this degree indicated only that a high standard had been reached in a large number of disconnected, academic, scientific subjects. Dr Barber pleaded for a larger representation of general practitioners on the General Medical Council, and amongst the teachers and examiners of students. Speaking of the teaching of future general practitioners by specialists under the present system, he declared "we are like bricklayers, who have been taught to mix their mortar by architects who have never touched a brick." He wished to see more thorough grounding in the common ailments, strict limitation of academic instruction, and a break down of the watertight compartments in which subjects were now taught. The medical course should involve less memorising, there should be more direction of the student's thinking powers, and less exhibition of the teacher's prowess. Academic instruction should be reduced to that minimum, which included only material directly applicable to practice, and such instruction should be undertaken in connexion with practical work. Anatomy and physiology should be more closely correlated, as should also pathology and bacteriology, and the connexion of these subjects with clinical medicine should be more adequately demonstrated. The anatomy course should be much curtailed. Dr Barber pressed the claim for instruction in the common ailments and social and preventive medicine, whilst agreeing that this would necessitate the surrender of some part of the present curriculum. He thought that the special subjects, of which only a general knowledge was needed, might be pruned.

Prof SYDNEY SMITH defended the curriculum at Edinburgh as being years in advance of that at any English school. The claims of preventive medicine were amply realised, at least in Edinburgh, and this was exemplified by the chair in child life and health, by the institution of school medical services, and by systematic antenatal supervision. Prof Smith contended that the premedical subjects—physics, biology, and chemistry—should be learnt at school. It was intended at Edinburgh University to institute a full five years' course, not including these subjects, which could then be learnt either at school or at the University in a course unconnected with medicine. Other changes shortly to be effected at Edinburgh were the curtailment of practical anatomy and

lengthening of the course in physiology, a more generalised instruction in biology, and a fuller course in applied physiology and anatomy, to be continued throughout the five years. The systematic teaching of medicine and surgery was to be largely transferred from the third to a later year, and instruction in these subjects was to be given in hospital, to ensure that the theoretical and clinical aspects should be not divorced. Further clinical instruction was to be given at the expense of vacations. Under the system now employed in Edinburgh, pathology and bacteriology were closely correlated with theoretical instruction in medicine and surgery, and with clinical work. Prof Smith strongly rebutted the suggestion that the teaching of special subjects should be curtailed. This instruction was, he asserted, essential and was general enough to be of interest to the general practitioner. He approved of the teaching of students by specialists, who, he asserted, were not unmindful of the needs of the general practitioner. The practitioner required the first class training, which the specialist could offer. While allowing that much could be said in support of the old system of apprenticing students to practitioners, he thought the present system fitted the student more fully for his manifold rôles, as scientist, artist, and priest. It was true that a student could not be a competent physician after five years' training, but the degree he obtained implied a solid basis on which he could build for the rest of his life.

After further discussion Dr CHALMERS WATSON, in summing up, supported Sir Francis Fremantle's plea for a reorganisation of the curriculum, and emphasised the necessity of instruction in preventive medicine.

THE ROYAL SOCIETY

THE only medical man among the 15 Fellows elected to the Royal Society on May 6th was Dr A. N. DRURY, lecturer in pathology in the University of Cambridge. He is distinguished for researches on the refractory period of, and conduction in, heart muscle, for studies of coronary circulation, and of the physiological action of adenosine. He has recently published jointly observations relating to the action of psychosin sulphate on bacteria, toxins, serum, and red blood cells. Mr Percival Hartley, D.Sc., does valuable work in close relation to medicine as director of biological standards at the National Institute for Medical Research, and as member of the British Pharmacopœia Commission.

We offer cordial congratulations also to Mr I. D. BERNAL, lecturer in crystallography, University of Cambridge, Mr A. C. CHIBNALL, assistant professor of biochemistry, Imperial College of Science and Technology, Mr G. R. CLEMO, professor of chemistry, Armstrong College, University of Durham, Mr H. V. FOX, professor of zoology, University of Birmingham, Mr W. E. GARNER, professor of physical chemistry, University of Bristol, Mr Sydney Goldstein, Ph.D., lecturer in mathematics, University of Cambridge, Mr H. L. HAWKINS, professor of geology, University of Reading, the Rev J. E. HOLLOWAY, lecturer in botany, University of Otago, Mr William Hume ROTHERY, D.Sc., Warren Research Fellow of the Royal Society, Mr T. G. MASON, Sc.D., of the Cotton Research Station, Trinidad, Mr J. R. MOIR, archaeologist, Mr M. L. E. OHPHANT, Ph.D., assistant director of research, Cavendish Laboratory, Cambridge, Mr C. F. A. PANTIN, Sc.D., lecturer in zoology, University of Cambridge, Mr D. R. PRESTON, Sc.D., deputy director of scientific research Air Ministry, and Mr E. C. STONER, Ph.D., reader in physics, University of Leeds.

GRAINS AND SCRUPLES

Under this heading appear week by week the unfettered thoughts of doctors in various occupations. Each contributor is responsible for the section for a month; his name can be seen later in the half yearly index.

FROM A MEDICAL ECONOMIST

III

WHEN children are all their toys the toys they cannot play with acquire a new significance. If the illness is very serious parents will scarcely endure the sight of these toys.

If the subject is discussed at all it is usually spoken of in terms of memory the idea being that the toys recall happier days. A dramatist however who is accustomed to secure his effects by means of material things as well as by means of words and gestures and expressions challenged this view recently in my hearing. It is not he said that the toys recall happier days in the past but that they demand happier days in the future.

Asked to explain himself he mentioned the wedding dress of which so much use is made by Sir James Barrie in his play *Quality Street*. A glimpse of that dress towards the end of the play makes many people weep he declared. Indeed the dress undergoes transmutation from act to act. At first it is just a wedding dress, at last it has become an actor endowed with a personality of its own and playing the chief part. The effect is tension—the hope that the wedding dress may yet be worn. Kill that hope and the dress loses its significance and becomes a relic.

I suppose that it can be said that in the same way the toys are unbearable because of the hope of recovery. If recovery does not take place the toys will become relics to which no tension will attach. Indeed, in that sorrowful case, they may as precious memories afford some consolation.

* * *

The point that seems to emerge is the tendency of all men and women to transform the materials which surround them into spiritual values. My hat in the latter shop and my hat upon my head are two widely different things. In the latter case side by side with consumption there is going on a process of change whereby what was an obvious and definite as a brick is becoming endowed with new mysterious qualities. Aristotle understood this process and detected in all things two kinds of substance—the accidental and the essential. The accidental substance of my hat happens to be black felt—it might have been straw or beaver or cloth; its essential substance is its hatfulness.

Aristotle devoted long and careful thought to the nature of essential substance and it is profitable still to ask oneself: What is a hat? What is a chair? and so on. The question soon convinces those who ask it that no definition in terms of material substances that is of accidental substances is possible. Nor will mere description afford a satisfactory answer. Whether we like it or not we shall find ourselves compelled to bring in the human element. Thus a hat is a covering for a head; a chair is something upon which to sit. Our definition is therefore teleological. Further it expresses a relationship between the designer and maker of the hat and the user—a relationship which if the hat is a good one is likely to be of a neighbourly character in the broadest sense of that term.

The hat in short, embodies an idea of a specific kind—namely usefulness. It is upon this idea that its owner's mind becomes fixed and it is this idea which if the owner lies ill, will occasion tension in the hearts of those who care for him. No piece of material unmade into an article of use is capable of producing such tension.

* * *

Aristotle called his study metaphysics. Another name was given to the same study by St. Thomas Aquinas who recognised in the products of craftsmanship an expression of the emotional relationship which exists between all men of good will. Essential substance for him was love and he saw the material universe therefore as a spiritual universe. *Verbum caro factum est*. Thus he recognised the capacity of material things to become vessels or containers of spiritual things nor was he disposed to establish any sharp differentiation between the vessel and its contents. The wood of which the chair was made was in fact, the chair. It had been subjected to a process of transubstantiation whereby retaining the physical properties of wood it had nevertheless acquired the metaphysical or as he would have preferred to say neighbourly qualities of a chair. It had acquired also the power to create tension in the form of a claim to be used.

St. Thomas supposed that this claim to be used was characteristic also of living forms and his ideas have an important bearing to day upon the attitude of men who cannot find employment. These men as we are all well aware produce a tension in the minds of their neighbours which recently was one of the most important elements in the political and economic life of the country.

Incidentally the identity of a man with his use to his fellows the transmutation of man into craftsman, artist, doctor is from the individual's point of view a very remarkable psychological process involving not only a discipline or if the word be preferred a morality but also an enthusiasm strong enough to carry the apprentice or student through the severe restraints of training. Such enthusiasm may not be self-conscious in the sense that a definite service is held in view from the beginning but since it seeks and finds some particular expression—making chairs or painting pictures or engaging in medical research—it is not the less on that account a surrender of purely selfish aims and so a kind of rebirth. Not only has the craftsman acquired power to transmute materials into spiritual values; he has himself also in the process been transmutated so that the greater his capacity to create the greater also is likely to be his contempt of personal considerations or personal selfishness. His body an accidental substance has thus become identified with the essential substance of love.

* * *

The fact of this transubstantiation is always present consciously or unconsciously to the doctor's mind in which invariably it produces tension. The doctor feels that the body disabled by sickness challenges him to restore it to its usefulness and so to secure the future. In responding to that

challenge the virtue goes out of him and he experiences, often, a sense of exhaustion disproportionate, apparently, to the effort he has made. In fact, his effort is creative in the true sense of that word, for the injury he essays to repair is not to flesh and blood only but also to the power which has transmuted flesh and blood into spirit.

That power, in the case of materials, lies outside of the material itself and must be imported into it. This is so obvious that none for a moment doubt it. But where flesh and blood are concerned such importation, being less obvious, is often overlooked. The body is self-repairing and so we discount the truth that external influences can be, and always are being, exerted upon the reparative process. One of these influences, as has been said, is that virtue which the doctor feels he has lost, another is the patient's own enthusiasm, that is to say the patient's own spirit. He who turns his back to the wall will not recover. It is difficult, in the face of that fact, to avoid the conclusion that the rebirth which is the finding of a vocation is the importing into a man's body of a new director, spirit, or soul, henceforward to be the man. Browning had knowledge of that incarnation when he wrote

'Lo a blade for a Knight's emprise
To fill the empty sheath of a man

And during many centuries the thought of Europe was focused upon it. Thus, it was believed that help given to anyone in distress was help given to the spirit in possession of the distressed person's body. The story of St. Christopher is a case in point, so

is the story of the crippled child who, on being rescued, was transmuted miraculously into the form of Christ. Doctors, on that showing, healed souls or rather helped souls to heal themselves. The conception of a secular medicine was almost wholly unknown.

* * *

It is of interest to note that, until frustration fell upon the world in the nineteenth century, poets and artists accepted the idea of immortality as self-evident. The poets of the frustration period are, without exception, minor poets. To be condemned to uselessness in unemployment or to perverted use in sweat shops is, apparently, to lose that sense of the supernatural which is the heritage of all men whose enthusiasm to serve their fellows has free play. In a world of frustration and perversion, moreover, the minds even of the free become darkened. Thus there would seem to be an interaction between economic conditions and the intimate texture of thought. The chairs in a museum, so long as they remain out of reach, are wood and upholstery, the men held prisoners of enforced idleness or perpetually vexed by fear, are so much flesh and blood—in Mr. Roosevelt's terrible phrase "industrial cannon fodder." Not for them the ecstasy of self-surrender to love of their fellows, the stern and inexorable morality inculcated by refractory materials, the growing sense of identity with powers which are not of this world, and so of emergence from the dimensions of space and time which flesh and blood, untransmuted, impose like a turnkey upon the human spirit.

PARLIAMENTARY INTELLIGENCE

THE FACTORIES BILL IN COMMITTEE

THE Factories Bill was further considered by a Standing Committee of the House of Commons on April 27th. Major LLOYD GEORGE was in the chair.

On Clause 68 (General conditions as to hours of employment of women and young persons),

Mr. SILKIN moved an amendment to provide that as respected young persons where the hours of employment included the hours from half-past eleven in the morning to half-past two in the afternoon an interval of not less than three-quarters of an hour should be allowed between those hours for dinner if dinner was taken in the factory or in a building of which the factory formed part, or one hour if dinner was not taken in the factory or such building. He said that hon. Members had recently been concerned with malnutrition, it was almost as important to secure that meals should be taken at the proper times as that they should be of the right quality and adequate in quantity. As the clause stood young persons might be employed for considerably longer than three hours without any guarantee of a proper meal time between half-past eleven and half-past two. The principle of the amendment was accepted as far back as 1912 and was contained in the Shops Act of that year.

Mr. G. LLOYD, Under-Secretary, Home Office, said that in 1912 there was no limit to the hours for women and the limit of weekly hours for young persons was 74. It was therefore imperative to see that there was sufficient time for lunch in the middle of the day. The position was very different under this Bill. It was a question of striking a compromise in individual cases all over the country.

Mr. BANFIELD said that he knew that even to day in thousands of workshops young persons got no proper meal time. Mr. LEWIS JONES said that every employer was anxious that proper facilities should be given for meals, but this amendment might interfere with the collective agreements which

had been made by trade unions and employers, in some cases providing for a minimum of one hour for the midday meal. Mr. SHORT said that if when drawing up welfare orders the Home Secretary would undertake to consider this aspect, particularly in respect of young persons, and make some conditions regarding the hours of meals that would meet the Opposition.

Sir JOHN SIMON, Home Secretary, said that he did not think that their existing powers as regarded welfare orders covered an actual mandatory direction as to the length of the interval for meals. The conditions in different kinds of work varied very considerably and it was better not to make a stiff rule which had to be applied indiscriminately. The effect of a discussion like this however, which would be noticed outside, was all to the good, because no one desired to rush people unduly, or to give them indigestion.

The amendment was negatived.

On the question that the clause as amended stand part of the Bill,

Mr. RHYD DAVIES said that the Labour Party would vote against the clause to show their dissatisfaction with it. He was a little alarmed that members of all parties failed to understand that this country was lagging behind some other industrial countries in the treatment of young people. He was ashamed at the way boys and girls were exploited in hotels. Mr. GRAHAM WHITE said he hoped the limit of working hours for young people would be nearer 40 per week than 46. Sir W. SMILES said it was unnecessary for young people under 15 to work in factories or to work 48 hours a week, but some workers in his constituency seemed to want their children to go to work at 14 and to work for 48 hours a week. Mr. VIANI said that many of the parents referred to by Sir W. Smiles had small incomes and that was why they were anxious for their children to go to work at an early age. When they realised that it would be for the ultimate benefit of their children that they should not start work so early

their attitude would change—Mr G MANDER urged that the Committee should consider the limitation of working hours for young people up to 18 years—Mr G BUCHANAN said that the clause was shockingly inadequate.

Sir J SIMON said that he had undertaken to put down a new clause modifying the hours of labour in factories for young persons between 14 and 18. He was glad that the Committee was going to make the modification in the hours of work of young people. He was sure it was right.

The clause as amended was ordered to stand part of the Bill by 34 votes to 18.

On Clause 70 which provides that with limitations pressure of work in any factory may be dealt with by the employment on overtime of women and young persons who have attained the age of 16.

Mr LILLIA SMITH moved an amendment to delete the reference to young persons who have attained the age of 16—Mr M McCORQUODALE supported the amendment. He said there was a general feeling in the country that young people ought not to work overtime—Mr VINT said that they should prohibit the working of overtime by young people under 18—Sir J TRAIL said that overtime was not economic, but it had to be worked in certain circumstances—Viscountess ASTON said that an overwhelming case had been made out for the amendment. Every organisation concerned with juveniles was alarmed at the effect that overtime had on them. The question had been asked whether industry could afford not to employ young people overtime, but the real question was whether the country could afford to overwork its juveniles—Sir W SMILES said that if overtime for persons up to 16 was prohibited there should at least be some exceptions such as apprentices in the engineering trade—Mr WAKEFIELD said that young persons between the ages of 16 and 18 should not be allowed to work for more than 48 hours a week.

After further debate

Sir J SIMON said a Factory Bill worthy of the name must within limits make improvements which would involve a certain measure of reorganisation. At the same time they must realise the difficulties. There would be very many cases which would never come up to the maximum and which he hoped increasingly public opinion would urge should be brought below the maximum. They wanted to know to what extent the provisions of the Bill would be an advance on present conditions. He had a list of some 31 trades. In the woollen and worsted trade in 45 per cent of the factories over 100 hours of overtime per year were being worked by women and young persons. In 20 per cent of the cases over 150 hours a year were worked. In 18 per cent over 200 hours and in 9 per cent over 300 hours. These were very big figures. They were of course a great deal short of what the present law allowed—Mr GIMMERS: Were those hours worked in addition to the 48 hour week?—Sir J SIMON answered in the affirmative. He gave figures showing the amount of overtime worked in various trades at present though he did not suggest that the present position ought either to be authorised by Parliament or made a standard for the future. But under the existing law over and above the 48 hours a week it was possible in a non-textile factory to have in the year 410 hours of overtime for women and young persons and in textile factories the figures were somewhere between 400 and 600 hours. At the present time those hours might not be worked in many factories but the figures in a large proportion of cases greatly exceeded that which this Bill would make permissible. The Bill would involve much reorganisation in many factories. In September 1936 the Ministry of Labour appointed a Board of Inquiry which after investigation recommended that from Jan. 1st 1937 the number of hours for all workers employed in the industry should be 48 per week. They recommended that paid overtime might be permitted in excess of 48 hours and they also recommended that in the case of women and

young persons under 18 overtime should be restricted to six hours per week and that the total overtime worked by any individual woman or young person in any calendar year should not exceed 96 hours. Those recommendations were subsequently embodied in a collective agreement between the parties in the industry and that agreement was now in force. He would remind the Committee that the Government had approved the view that there should not be any overtime at all for juveniles between 14 and 16. He would give figures to illustrate that change. The present legal hours for young persons between the ages of 16 and 18 in a year were 7600 hours, cutting out one week for a statutory holiday. Under this Bill they were going to reduce that total to 2550 hours—10 hours a week less in a 51 week year. That seemed to him substantial. In addition they were laying down that overtime should be limited to 100 hours and that there was not to be more than 30 weeks in which it could occur and if it occurred to the maximum extent permitted in one week it would not be spread over more than 10 weeks. What more could the Government properly and wisely do? He did not attach much importance to the argument that they might have a breakdown or that two or three boys might be away through illness. It was the industries which depended on juvenile labour which mattered and there were something like 500,000 people between 16 and 18 engaged in factory work of some kind or another.

It seemed to him that there were two qualifications which should be made on the proposals of the Bill. (1) That even this limited amount of overtime ought not to be allowed in an industry which was injurious to the health of young people. (2) That if as a result of inquiry the view was taken that overtime could be reduced without serious detriment to the industry the Secretary of State might make regulations to that effect.

Mr SIMON said that Sir J Simon had given them nothing and had entirely ignored the collective opinion of the Committee.

The amendment was negatived by 31 votes to 19.

A further amendment to add a provision that no young person in a factory should work more than 50 hours overtime in any calendar year was also negatived by 33 votes to 21.

The Committee adjourned.

The discussion of Clause 70 was resumed by the Committee on April 29th.

Mr G MANDER moved an amendment to limit the overtime to 20 weeks in any calendar year.

Sir J SIMON said he would be prepared to agree to the figure of 30 being reduced to 20 if that was thought to be an advantage. They wanted something in the Bill to show that overtime was not intended to be the rule.

The amendment was agreed to with the figure fixed at 25.

Sir J SIMON moved a new subsection to provide that if representations were made to the Secretary of State concerning any class of factories that having regard to the particular circumstances the overtime allowed under the clause could be reduced without serious detriment to the industry he might direct an inquiry to be held and make regulation for modifications to secure a reduction of overtime worked by women and young persons in such factories.

The new subsection was agreed to.

Sir J SIMON moved a further new subsection providing that if he was satisfied that the business in any class of factory involved the overtime employment of different persons on different occasions to such an extent that the provision limiting overtime would as respects a substantial number of factories of that class be unreasonable or inappropriate he might make modifying regulation. Such regulations would secure that no woman should be employed overtime in a factory for more than 50 hours and no young person for more than 40 hours in any calendar year and that no woman or young person

should, except as otherwise provided in the regulations, be employed overtime in the factory for more than six hours in any week or more than 25 weeks in any calendar year.

The new subsection was agreed to and Clause 70 as amended was ordered to stand part of the Bill.

The Committee adjourned.

The Factories Bill was further considered by a Standing Committee of the House of Commons on May 4th with Major LLOYD GEORGE in the chair.

On Clause 78 (Exceptions as to male young persons employed in shifts),

Sir JOHN SIMON moved a series of amendments which he said were designed to meet the wishes of certain members of the committee. This clause was directed to industries which required to be carried on continuously day and night. The present law did allow exceptional provisions to be made for night work in processes which required continuous attention, even in the case of young people under 18. He had come to the conclusion, especially in view of what the committee had done earlier in the Bill, that it would not be right to make any exception at all as regarded young persons under 18. They might have to do it in the case of youths between 16 and 18, but it was not necessary to do it for anybody younger and he proposed to make that clear in an amendment. Provision would also be made for an interval of not less than fourteen hours between shifts. Young persons over 16 would be periodically examined by the examining surgeon in the conditions of the work in order to see if they were fit for employment at night.

Several amendments carrying out the proposals indicated by the Home Secretary were agreed to.

Mr A. SHORT moved an amendment to delete the part of the clause which allows young persons to work on the four-shift system between 6 A.M. and 10 P.M. on Sundays.—Sir J. SIMON said this was a system employed in certain trades and undoubtedly it appealed very much to the workers employed under it. He thought that they ought to give fair latitude to a system which had considerable practical advantages. The amendment was negatived.

On the question that the clause stand part of the Bill,

Mr DENMAN said that night work for young persons was so well-accepted in industry that there was no chance of abolishing it at this stage, but he thought that it was desirable that it should not go out that that committee really approved of night work for young people as a permanent system. Medical evidence was lacking to show that it was injurious to the young persons themselves, but the point was that it was injurious to them as adults. He had had statements to that effect not only from a doctor of a London hospital who had experience of the effects of night work, but a factory inspector told him (Mr Denman) that although they could bring no kind of evidence of ill health among young persons they could see the result in adults by whom they were surrounded every working day. An authoritative statement of the case appeared in THE LANCET (Feb 20th, 1937, p 451) after the second reading of this Bill. It was a very interesting editorial article which he wished hon. Members had read. It pointed out the simple fact that the evil appeared later in life and it made this a very interesting point in arguing that it was biologically unsound to subject young persons between 16 and 18 to the strain of night work. He felt sure that as we rose in civilisation, and as we paid more attention to the importance of youth in building the nation, we should raise this age from 16.—Mr VIANT said it might not be possible to produce medical evidence, but from his own experience he knew that night work was not good for the health of anyone. He deplored the fact that the committee had not seen the wisdom of inserting in this clause a proviso prohibiting night work for young persons up to the age of 18 at least. This was the one black spot on the clause.—Sir E. GRAHAM-LITTLE said that

no doubt he was asking for a counsel of perfection, but that did not deter him from making his protest against working young persons on night work. He would give some recent figures from an authoritative book just published by Dr Vernon, an experienced research worker, whose conclusions had been accepted by the whole medical profession. Dr Vernon showed that there was an extraordinarily high mortality-rate in the age-group of males between 15 and 19. He dealt with large figures because the unit was 40,000. In this age-group the number of fatal accidents was very high, they constituted one-fifth of the deaths in that group. The Departmental Committee on the Employment of Young Persons in their report recommended a general prohibition of night employment for a period of eleven hours, including the hours of 10 P.M. to 6 A.M., for young persons. The incidence of accidents during night work was also discussed in Dr Vernon's book in a most judicial way. He said that on the whole accidents were more frequent during night work than during day work. In the iron and steel industry the rate was sometimes 50 per cent higher. If they had a combination of what they might call an accident-prone group, boys between 15 and 19 years of age, and an increased rate of accidents in steel works, were the committee really comfortable in going forward with the suggestion that these boys should work at night in steel works? He thought there was a strong case for reconsidering this matter.—Viscountess ASTOR said that Sir E. Graham Little had made out a very good case against night work for young people. If the Home Secretary would raise the age to 17 he would go a little way to meet the case. She could not possibly vote for working children of 16 on night work. The clause was ordered to stand part of the Bill by 24 votes to 13.

On Clause 89, which provides that the period of employment of male young persons who have attained the age of 16 may begin at 5 o'clock in the morning in that part of a bakehouse in which bread making is carried on,

Mr J. W. BANFIELD moved the deletion of the clause. He said that there was no need for it in the trade.

Mr G. LLOYD, Under-Secretary, Home Office said that the 5 A.M. start for boys in bakehouses had almost disappeared in England, but it was not uncommon in Scotland, where apprenticeship started at 16 years. The Committee should pass the clause on the understanding that it might be modified when the report on the Committee on Night Baking was available.

The clause was ordered to stand part of the Bill.

On Clause 92 (Certificate of fitness for employment of young persons),

Sir E. GRAHAM-LITTLE moved the first of a series of amendments designed to enlarge the scope of the clause by enlarging the class of young persons who would be the subject of medical examination before being engaged in factory work. He said that the amendments were all attested by medical authorities.—Mr GRAHAM WHITE hoped the Home Secretary would see his way to meet the point put forward in these amendments. There seemed to be no reason at all, and in fact every reason to the contrary, why the present provision in the Bill which limited the examination to young people under 16 should not be extended. He was advised that it was particularly valuable and necessary in the case of female young persons between 16 and 18. In any case, a single examination within a few days of the entry into employment was a very inadequate safeguard. Those who put forward these amendments urged that the scope of the clause should be enlarged by making the examination apply to all those up to the age of 18, and also that the examination should be repeated as a safeguard from time to time.

Sir J. SIMON said he did not deny that there were fair arguments for raising the age and the Factory Department and medical officers of the Home Office were not in the least disposed to pour cold water

on that idea if on balance it was a good one. The clause required that every young person entering a factory under the age of 10 should be examined by the examining surgeon. If there was any doubt as to fitness for employment the examining surgeon would re-examine. The advice given to him by the responsible medical authorities who were connected with the factory system was that these examinations were sufficient to secure that any young person under 10 who was suffering from defects would be warned off that employment and have to find his living elsewhere. It was intended also to make the examination a much more satisfactory one than previously. There was also to be a liaison between the examining surgeon and the school medical officer. There was a second point on which his medical advisers felt very strongly indeed. They were satisfied that there might be a considerable amount of feeling on the part of the older juveniles if it was said that because they chose to come into factory life they would by law be put under compulsory medical examination at intervals. They were making improvements in the medical inspection and it would be a mistake to go further.

After further debate the amendments were with drawn and the clause was ordered to stand part of the Bill.

The Committee adjourned.

PANEL DOCTORS FEES

In the House of Commons on Thursday May 6th, Mr RICH DAVIES asked the Minister of Health whether he was now able to state the terms of reference and the personnel of the tribunal to inquire into the fees paid to panel doctors under the national health insurance scheme.

Sir KINGSLEY WOOD replied that the object of the Court of Inquiry appointed by the Secretary of State for Scotland and himself was to investigate the question whether any and if so what alteration ought to be made in the amount of the doctor's capitation fee having regard to any changes since 1924 in the cost of living, the working expenses of practice, the number and nature of the services rendered to insured patients, and other relevant factors. He was glad to say that the services of the following gentlemen as members of the court had been secured: the Right Hon Lord Amulree O.B.E., K.C., LL.D. (chairman); Mr Thomas Howorth A.O.A. and Mr D. H. Robertson M.A., Mr F. H. Phillips O.B.E. of the Ministry of Health to be Secretary.

The following are the terms of reference of the Court of Inquiry:—

To inquire and report to H.M. Government whether any and if so what alteration ought to be made as from Jan. 1st 1938 in the amount of the capitation fee (per insured person per annum) on the basis of which the Central Practitioners Fund under Article 10 of the National Health Insurance (Medical Benefit) Regulations 1936 and the corresponding Scottish Fund under Article 10 of the National Health Insurance (Medical Benefit) Consolidated Regulations (Scotland) 1929 is calculated having regard to any changes which may have taken place since 1924 in the cost of living, the working expenses of practice, the number and nature of the services rendered by insurance practitioners to their insured patients and other relevant factors. The inquiry is to proceed on the assumption that as from Jan. 1st 1938 employed persons under the age of 16 will have become entitled to medical benefit by virtue of amending legislation but that the conditions would not impose any obligation upon the practitioner to issue medical certificates to these persons. The capitation fee is not to include any payment in respect of the supply of drugs and appliances or any payment to meet the special conditions of practice in rural and semi-rural areas. Payments to insurance practitioners in respect of these matters are the subject of separate arrangements and are outside the scope of the inquiry.

Mr RICH DAVIES asked whether the right hon. gentleman contemplated that the report would be

issued soon enough to admit of the Bill which he had promised, being presented to Parliament and passed into law before the summer recess?—Sir KINGSLEY WOOD hoped that would be so.—Mr THORNTON asked whether the inquiry was not made necessary by the fact that the right hon. gentleman could not reach an understanding with the doctors.—Sir KINGSLEY WOOD thought it should rather be regarded as a friendly arrangement to have this matter dealt with by independent people. There were discussions between the British Medical Association and himself on this matter and this appeared to be the best means of dealing with it.

DIETARY SURVEYS AND NUTRITION POLICY

In the House of Lords on May 5th Viscount ASTOR drew attention to the report of the Advisory Committee on Nutrition to the Ministry of Health and in view of the recommendations of that committee asked (a) whether the Ministry of Labour in pursuance of the purpose of the cost of living index would include an inquiry into dietary surveys and if so how many families would be concerned in this inquiry, and what steps were being taken to ascertain the family incomes so as to correlate this inquiry with that proposed to be undertaken by the Registrar-General and an independent statistician; (b) whether steps had been taken by the Registrar-General to carry out this proposed inquiry into the constitution of families by age, sex, occupation and locality and into the distribution of family incomes; (c) what local authority in urban and rural areas respectively were conducting dietary surveys in England and Wales and in Scotland respectively, and about how many families would be covered in each country. The noble Lord moved for papers.

Lord ASTOR said the main cause of the evils of malnutrition was undoubtedly poverty. By malnutrition he did not mean hunger or starvation but a degree of ill health or of subnormality due to malnourishment and in other cases actual bad physical development due to malnutrition in early youth. So that the problem really was one of purchasing power. Where they had a small income they had a small expenditure on the essential foods—the health giving foods. It was a serious problem because a large number of people who showed the effects of malnutrition could not be put right. It was a problem which arose very largely because of malnourishment in youth. A certain number of cases of maternal mortality were due to malformed pelvis. That was largely due to the malnutrition of the woman when she was a child. The difficulty was that they had to get into their minds an entirely new standard. He had no doubt that at the beginning of last century medical officers were perfectly satisfied with the housing conditions in our large industrial centres. To-day those same medical officers were unanimously agreed that those houses must be pulled down as slums. They had to bear that in mind when they saw quoted as they so often did reports from medical officers of health to the effect that there was no problem of malnutrition. Those who made such reports were out-of-date; they were not acquainted with the new knowledge—the new findings of science. After making all the allowances for exaggeration and over-statement one could say without fear of contradiction that there was a real problem of malnutrition affecting millions of people of this country. In the Advisory Committee's report reference was made to methods of clinical assessment. Did the Ministry contemplate undertaking an investigation of the clinical aspects in direct correlation with the dietary surveys which it was proposed to make? The main function of agriculture, certainly in this country, should be to see that the right sort of food were provided at the right costs for our people. We should aim at having our agricultural policy upon the methods of the farmers who are making money rather than pay so much attention to the shouts and protests of the farmers who were not making money or who were losing money or who

did not want to change their methods in order to move with the times. The Advisory Committee's report had indicated the importance of the nutrition of milk as an article of consumption and diet. It was the foundation of good nutrition. This country was surely a suitable and good country for milk production and yet after four years of the Milk Marketing Scheme they found a very low consumption of milk, retail prices the second highest in the world, and the dairy farmers were all discontented. There surely must be something fundamentally wrong with a scheme that had such results. The first thing wrong with the Milk Scheme was the structure of the governing body. If they were dealing with armaments nobody would suggest that they should go to the armament firms and say "We will pass an Act of Parliament giving you statutory power to form a monopoly ring. You can elect your own governing body, and if any armament manufacturer dares to cut prices you can put him in prison, and we will have no Ministry of Munitions to supervise." That was being done under the Milk Scheme. The second thing which was wrong was that the Milk Board had used its powers in order to develop new industries in this country. These activities of the Milk Board had been condemned by the Milk Commission which had recently been sitting and also by the Milk Council, but the result of all this was that the price of milk in England to day was much too high.

The Minister of Health, as soon as the Report of the Advisory Committee was published, circulated all local authorities drawing their attention to the recommendations of the report of the Committee and urging them to make more provision for supplying milk to mothers and children. Why should the Minister of Health ask the ratepayers to spend money in buying milk which had been artificially put up in price by another colleague in the Cabinet? The Minister of Health must get his colleagues in the Cabinet to give the country reasonably cheap milk—milk produced by an efficient dairy industry—and then he could justifiably ask the local authorities to accede to his request. Their aim should be to reduce the price of milk by 8d a gallon, which would bring it down to 2d a pint, instead of 3d, which was the present cost. Even after they had done that, they would still have to have subsidised milk for large sections of the community. They could reduce the cost of milk by one-third. First of all they could save 3d a gallon by stopping the subsidy and they ought to be able to save 3d or 4d on distribution. Ulster had a milk scheme which had been eminently satisfactory because the controlling influence on the Ulster Milk Board lay with the members nominated by the Government though the producers were represented too. Also the milk was compulsorily graded according to its hygienic quality, and farmers were paid according to the grade they produced. It worked automatically and, as a result, in Ulster the price of milk was very much lower than it was here. As to distribution he would advocate a bold policy. He found no reason why the nation should not have control over the wholesale distribution of milk. In Scandinavian countries they had what was called the Oslo breakfast—every child who arrived half an hour before school opened got a free breakfast of a glass of milk and bread and butter or margarine with fruit and also a cereal if possible. He (Lord Astor) did not necessarily advocate free meals to all children, or say all children should have to pay for them. He thought they must contemplate subsidising food, not only for children of school age but also for the pre-school child in nursery schools. He was glad to notice that in his circular to local authorities the Minister of Health urged local authorities to help mothers at maternity centres. If they were to subsidise the consumption of these protective foods so that mothers, pre-school children, and school-children had enough of them, in the next generation the country would have a very much stronger and healthier race and a much more prosperous agriculture.

LORD SNELL said that there was something incongruous in the fact that at a time when they were undertaking great national rejoicings they should have to confess that a large proportion of our population was actually underfed. The Government and people about the country seemed to be pursuing a false way of approaching the problem, in that they were putting the question of gymnastic exercises and of keeping fit before the question of feeding. It was good to see the grace of young life in gymnasium and elsewhere, but inflated muscles did not compensate for weakened hearts, and jerry-built manhood of that character was not what the nation required. The proposals made by Lord Astor should be very seriously considered by the Government. The right way to begin was first of all to feed the children and the mothers. There was no need to haggle as to whether milk should be 3d or 6d per pint, or what the profits should be. It was the business of the community to feed its children. What the children required was milk and if it could not be paid for, the Government should provide that milk free for children and also for expectant and nursing mothers—LORD ELSTISLEY said that the Milk Marketing Board and the various committees connected therewith had prevented a certain collapse of the milk industry in this country. It had undoubtedly saved from disaster 135,000 milk producers—LORD NOEL BUXTON said that the experience of such bodies as the Save the Children Fund confirmed the plea that Lord Astor had made. He was glad that the Government in dealing with the problem had not been governed solely by the theory of parental responsibility, but had ensured a better start in life for countless children who otherwise would have suffered. All the evidence showed that that policy ought to be carried further—Viscount BLEDISLOE said that as regarded young children we in this country might learn a great deal more than we had yet learned about their care, and particularly the supply and treatment of milk, from New Zealand, where the Plunket or Truby King system had been in use for a great many years and where the vital statistics showed the enormous advantage to the infantile population as the result of this system carried through not only for the benefit of nursing mothers but for the benefit of both mothers and children in what were known as the Karitane Homes which were to be found all over the Dominion.

The Bishop of NORWICH said that he thought they were apt to confuse the nutritive value of milk with the other side of the milk question. He could not feel certain that the restrictions now put upon the quality of milk were really as necessary as medical men told them they were, and the dairy farmers were in consequence striving to reach a standard that after all the medical man might one day pronounce to be unnecessary. He had never yet seen anything really convincing to show the relative nutritive value of plain milk, pasteurised milk, and boiled milk. Children did not like boiled milk. No one had told them in a really authoritative way what was meant by pasteurisation. It was found also that in many cases those who did drink raw milk without contracting disease seemed to flourish more on the plain raw milk than upon milk that had been treated in any way. He could not persuade himself that our system of bottling, and so on, was really satisfactory in delivering pure milk to the child. There were so many opportunities of lapses. He believed that a great impetus would be given to dairy farming if the standards demanded were readily intelligible and easily carried out, if they became intelligent pupils and not the slaves of laboratory experiments made on the side of medicine, and if they were able to take a broader common-sense view of the whole situation.

LORD DENMAN said that the Ministry of Health recently circulated maternity and child welfare authorities asking them to review arrangements for the supply of milk to mothers and to young children. The Minister suggested that "scales should be framed as not to render it difficult for mothers to

take advantage of the authorities arrangements." A society which he (Lord Denman) represented complained that this instruction was too indefinite and that in some areas mothers and children under school age could not obtain free milk unless family income fell within a very low limit. In some cases the income, after deduction of rent for a family of five must be as low as 25s or even 22s 6d before free milk was granted. He hoped that the Minister might be able to issue more definite instructions on that point or that he might ask his Advisory Committee to draw up for the guidance of local authorities a scale based on the present knowledge of food requirements. The Minister's circular valuable as it might be in some respects went only a small way towards securing increased consumption of milk by mothers and young children.

Viscount GAO, replying for the Government said the investigations into nutritional problems fell into three simple categories—namely what the people ought to eat what they did eat and methods of improvement. The report of the Advisory Committee showed that certain foods especially milk, dairy products green vegetables and fruit were essential to health. They had protective value because they stopped certain definite deficiency diseases and also built up the resistance of the body to other forms of disease. It seemed difficult to exaggerate the importance attached by these experts with a unanimity rare among experts to the value of these protective foods, especially in infancy and the Government entirely accepted the conclusions of the report on that subject. It was satisfactory to know that the average consumption per head of most foodstuffs had increased since just before the war and that with one exception there had been a general improvement in the quality of the national diet. It was also satisfactory to know from the report that the supply of energy-giving foods available for the nation was more than was considered adequate by the Committee of the League of Nations. The Government fully accepted the recommendation of the Advisory Committee that much more information was desirable and they were prepared to collect it. But such inquiries were not always so easy as was sometimes imagined. What the Government had in mind was really a three-fold inquiry. There was first the Ministry of Labour inquiry in connexion with the cost of living index figure. For this it was hoped to procure the weekly budgets of 10,000 families taken over four separate weeks in various parts of England Wales and Scotland. These families would all come from the classes covered by the national insurance schemes. Naturally the inquiry would comprise information besides that relating to food but the special information relating to food would be summarised separately. Family budgets were made up as a rule in rather a rough and ready way. For certain purposes calculations of that sort might be quite sufficient but when they were trying to find out about the number of calories vitamins carbohydrates and so forth that were consumed they could not afford to be rough and ready. Accordingly they proposed to check these results by another inquiry called a "quantitative dietary survey" which would be of a much more detailed character. It was in fact already in progress and would eventually embrace 500 families of which 200 would come from Scotland. This might appear to be a small number but he would emphasise that a dietary survey of this kind meant that a qualified investigator had to spend much time in the homes of these families weighing up all the food which came into the house and what was left over estimating its composition down to the constituents even of the cakes and puddings and so forth and noting any wastage. He thought they ought to be grateful to these families for co-operating with their inspectors to the extent that they had done. He (Lord Gage) could not give the dates by which the whole inquiry could be completed but the results of the surveys which had already taken place at Newcastle-on-

Tyne, affecting 60 families had been published some months ago. There was another inquiry affecting 205 families in the West Riding the results of which would probably be published by the end of this year. These were not included in the 500 families which he had mentioned. An inquiry had already been begun in the Isle of Ely Surrey Glossop Aberdeen and certain industrial towns near Glasgow. It would be extended to Somerset Glamorgan Carmarthen Cardigan Aberdeen County Banff Kincardine Dumfries and the Border Counties. The next step after that would be to take out from the last census figures a definite proportion say of one in five hundred or one in a thousand of all the family census schedules and this they expected would show roughly after certain allowances had been made for altered conditions the distribution of the population according to occupation. These statistics would then be compared with information in the possession of the Ministry of Labour with regard to wage rates current in such occupations. It was hoped that on this basis they would be able to correlate to some degree all these inquiries and to present a working analysis of how the incomes of various classes of the community were divided, with special reference to food.

He would now return to the third and most controversial question of how they could improve. He admitted that three-quarters of the problem must turn on the capacity of the people to buy the right foods and that therefore food must be cheap. It was equally important that the people should have the wages to pay for the food. During their period of office the number of those in employment had increased by about 2,000,000. In one year over 2,300,000 had benefited from an increase of wages amounting to nearly £100,000 a week and the price of essential foodstuffs in spite of some rather wild statements to the contrary had during the last five years remained fairly steady. Following the unanimous advice of their experts the Government had been particularly active in connexion with the supply of milk on special terms to special classes of the community principally school-children expectant mothers and infants and unemployed in the distressed areas. There was also schemes for the provision of free and cheap food to similar classes. The scheme for providing school-children with cheap milk which started in 1934 had now been made available to 92 per cent of all the school-children in the country and 2,000,000 school-children were making use of the scheme. Free food might also be supplied to any child showing signs of requiring it though certain safeguards obviously had to be observed in this connexion. Over 400,000 children received free milk last year and 2,000,000 free meals were consumed by 14,100,000 children. About £700,000 was paid to the local authorities by the Government in specific grants towards these schemes. As to the mothers and infants at all antenatal and child welfare centres and at all antenatal clinics free food and milk might be supplied under medical advice to necessitous cases special attention being paid to malnutrition rickets and so forth. There had been a large extension of these centres in the last few years and the attendances had greatly increased. Two hundred and ninety-seven thousand mothers now attended the clinics. Last year the equivalent of about 7,000,000 gallons of milk were distributed free or at less than cost price according to the means of the applicants. Schemes for cheap milk had been adopted in the Special Areas the cost of which was borne in part by the Councils alone instead of by the local authorities.

As to the future he could undertake that the Government would press forward with all these schemes to the best of their ability. They had recently issued a circular inviting all the local authorities to review their arrangements under the Maternity and Child Welfare Acts and to improve and increase their diet and especially the milk diet of expectant mothers and children. They had also laid emphasis on the

necessity for securing the purity of the milk. A publicity campaign was contemplated in the autumn to make better known the existence of the facilities available at welfare centres. The Government had also put another £5,000,000 into the general pool available under the block grant scheme and by the reweighting of the formula they felt that the necessitous local authorities would be placed in a better position to bear their part of the financial burden. In conclusion he would like to say one word of what he might call subdued optimism. In the seventies of last century there was a death-rate of 21.4 per 1000. In 1930 the death-rate was 12.1 per 1000. In the nineties the death-rate of children under one year was over 150 per 1000. By 1930 this figure had been reduced to 59 per 1000. The death-rate from tuberculosis was less than half what it was twenty-five years ago, and from rickets less than half what it was five years ago. Of the 1,700,000 children inspected by school medical officers during 1930 the nutrition of 14.6 was said to be excellent, 74 per cent were normal, 10.5 per cent slightly abnormal, and 0.7 per cent bad. These figures, he thought, showed that this country was making real progress, and were a general encouragement to further effort. The Minister of Health had shown the profound interest which he took in the problem of nutrition. Setting aside all questions of human sympathy, a vast amount of administrative effort which was now being spent on the cure and care of disease would obviously be immensely reduced if illness could be prevented as the experts claimed it could be, by better nutrition. The Government had to assist them bodies of unimpeachable reputation such as the Medical Research Council and the Advisory Committee on Nutrition presided over by Lord Luke. All these factors seemed to indicate that if prosperity could be maintained progress in nutrition would also be maintained with increasing impetus.

VISCOUNT ASTOR, in congratulating the Government on what they had done, urged them not to sit back satisfied, but to realise that there was still a great deal that required to be done.

The motion for Papers was withdrawn.

CONTRIBUTORY PENSIONS (VOLUNTARY CONTRIBUTORS) BILL

On the motion for the third reading of the Widows', Orphans', and Old Age Contributory Pensions (Voluntary Contributors) Bill in the House of Commons on May 6th,

SIR KINGSLEY WOOD, Minister of Health, said that this scheme had a very wide popular appeal and it would fill a definite gap in our existing social insurance system. So far as the insurance provisions were concerned, the Bill provided the best and cheapest and safest policy of the kind in the world. He hoped that it might soon be possible to introduce another measure which would fill another gap. The Government had already announced their intention to introduce national insurance legislation to entitle boys and girls to receive medical benefit immediately on taking up employment after leaving school instead of having to wait until the age of 16 as at present. The introduction of this measure had been postponed pending the settlement of the terms of remuneration of the medical practitioners. That question was going to be settled, he hoped, quite amicably and certainly by agreement, between the medical practitioners and himself by an arbitration court at an early date. He desired to see a good many gaps filled, but they had to recognise that the social protection of the people must be an evolutionary process. There were in Great Britain to-day more than 19,000,000 persons insured under the Contributory Pensions Acts and if their dependents were taken into account it might be said that 75 per cent of the population were protected by this scheme. Already 4,250,000 persons had participated in the pensions and allowances, and £350,000,000 had been

paid out in benefits to persons under 70, while a further £170,000,000 had been paid to persons over 70 entitled to pensions by virtue of the Contributory Pensions Acts. The Exchequer contribution to the cost of pensions payable to persons under 70 was no less than £15,000,000 during the financial year 1936-37 alone. These contributions rose by £1,000,000 a year to £21,000,000 in 1942-43, at which figure they would remain until 1945-46, after which Parliament was to determine the further subventions required. The cost to the Exchequer in 1936-37 of pensions to those over 70 payable by virtue of the Contributory Pensions Acts was approximately £25,000,000 and the cost of the pensions to people over 70 payable under the Old Age Pensions Acts by reference to means was approximately £18,400,000. To those figures must now be added the considerable cost of this new scheme. If there were 700,000 entrants—and he would be disappointed if there were not—then, if they excluded the consideration of the financial commitments in respect of pensions for those over the age of 70, the Exchequer liability would be £43,000,000. They could legitimately claim that no country made such a financial contribution as we did or had a wider range of social protection for its people.

The Bill was read the third time and passed.

NOTES ON CURRENT TOPICS

In the House of Lords on May 6th the Royal Assent was given to the Local Government (Financial Provisions) (Scotland) Act, the Maternity Services (Scotland) Act, and the General Cemetery Act.

Both Houses of Parliament adjourned on May 6th for the Whitsuntide recess. The House of Lords will reassemble on May 25th and the House of Commons on May 24th.

QUESTION TIME

THURSDAY, MAY 6TH

Coöperation between Public and Voluntary Hospitals

MR SORENSON asked the Minister of Health whether, in view of the report of the Voluntary Hospitals Commission and of the increasing contributions by public authorities to voluntary hospitals, he would require that the finances of voluntary hospitals should be pooled and that greater coöperation should be effected between voluntary and public hospitals.—SIR KINGSLEY WOOD replied: I have noted with interest that the Voluntary Hospitals Commission, while not recommending the immediate pooling of hospital finances, suggests the creation of regional funds, but I have no powers in this matter, which is one for consideration by the governing bodies of the hospitals. I may assure the hon. Member that I shall continue to encourage coöperation between voluntary and public hospitals, which, I am glad to say, is already increasing steadily.

Cleanliness in Handling of Bread

SIR NICHOLAS GRATTAN DOYLE asked the Minister of Health whether, after the introduction of the recently announced legislation to provide that milk for human consumption should be clean and bacteriologically pure, he would consider means by which to ensure that bread for human consumption, whether in course of distribution or whilst held for sale, should at all times be covered or wrapped in dust proof material to reduce uncleanness by handling.—SIR KINGSLEY WOOD replied: I appreciate the advantages from the point of view of cleanliness of the wrapping of bread but on the information before me I am not satisfied that a general requirement on the subject is necessary.

MATERNITY CLINIC FOR SUNDERLAND.—Sunderland health committee have approved in principle a scheme for erecting a maternity clinic in the east end of the town. An application will be made to the commissioner of the Special Areas for a grant towards the estimated cost of £10,000.

PUBLIC HEALTH

Circular on Maternal Mortality Report

IN a circular (No 1622) addressed to maternity and child welfare authorities on May 7th the Minister of Health draws attention to the report on maternal mortality summarised in THE LANCET last week (p 1126) especially to the recommendations emphasising (1) the importance of team work (2) consultant services (3) emergency units (4) maternity accommodation (5) antenatal services (6) postnatal services (7) auxiliary services (8) the keeping of records (9) education. The Minister notes that recommendation (2) in section A of the report contemplates that each local supervising authority under the Midwives Acts should in consultation with the local medical profession be empowered to take steps to ensure that the best local obstetric skill is made available in all cases in which midwives are required to call in a doctor. An alteration in the rules of the Central Midwives Board would be required before effect could be given to this recommendation and the Minister has asked the Board to consider the recommendation. He is also inviting the views of the associations of local authorities concerned and of the British Medical Association on this recommendation (see below). As to the three subjects recommended in the report for further study the Minister is in communication with the Medical Research Council on the suggestions that further research should be undertaken (a) with a view to the discovery of a reliable prophylactic treatment for puerperal sepsis, and (b) into the possible influence of the dietary upon childbearing. With regard to the third subject recommended for further inquiry that of abortion the Secretary of State for the Home Department and the Minister are appointing a committee to inquire into the prevalence of abortion and to consider the steps necessary to secure the reduction of maternal mortality and morbidity arising from this cause. The Minister asks each authority to give early consideration to the report and to the suggestions made in the circular and inform him of the action they propose to take.

THE VIEWS OF THE BRITISH MEDICAL ASSOCIATION

The British Medical Association has already in an addendum to the annual report of their council published in the Supplement to the *British Medical Journal* of May 8th said that the suggested amendment of the rules of the Central Midwives Board is not one that could be approved or supported by the Association. The proposal that midwives in the future would in cases of emergency be able to call for the services only of certain selected practitioners and that local authorities should be advised and encouraged to make such selective lists would in the opinion of the Association aggravate the disadvantages of the present situation. They call attention to three inconsistencies which might immediately arise.

(1) Many insurance practitioners would be by statute charged with the duty of attending or accepting responsibility for insured women from the time conception took place up to the moment that labour pains began and again from ten or fourteen days after delivery while they would be prohibited if the mother wished to take advantage of State provision from having any thing to do with her in the intervening period.

(2) There would be practitioners in some areas freely available for attendance in the case of midwifery emergencies while in a neighbouring area they might

be debarred from any such attendance owing to alleged incompetence or inexperience.

(3) In one area in 3 per cent of all confinements the emergency was such as to require the immediate attendance of a practitioner in order to save the life of mother or child so that in many rural areas the midwife might by rule be prohibited from calling in the most easily available practitioner.

An alternative plan which the council of the Association greatly prefers and would urge upon the Minister is that each local authority should prepare a list of local medical practitioners who are willing to make themselves available to be called in by midwives that such practitioners collectively should at once be brought into close touch with the consultant obstetricians recognised for the service in the area and should be kept in frequent association with those consultants with a view to the appreciation of their several spheres of action to instruction as to the proper course of action and the means of securing appropriate help in cases of difficulty and to the mutual and confidential investigations as to the causes of difficulty or of death. If thought necessary it might be arranged that if a practitioner's name was to continue on the list beyond a certain period of years he should have to undertake a more formal post-graduate course in obstetrics and it might be possible to establish some machinery by which the name of a practitioner whose work proved unsatisfactory might be removed from the list. In some such way as this the council believes that local lists would be established in a less objectionable and less difficult way than in any other and that the lists so established under these conditions would prove to be more satisfactory and successful in maintaining an adequate service. The council suggests that such it is should be established at the time or shortly after the time at which the Midwives Act comes into operation.

Supervision of Midwives

With another circular (1620) the Minister encloses for the information of local supervising authorities under the Midwives Acts (England) copies of the regulations¹ which he has made prescribing the qualifications of persons appointed to exercise supervision over the midwives practising in their areas. The regulations will come into operation on June 1st next and apply only to persons appointed as supervisors of midwives on or after that date. The object of the regulations is to ensure that persons appointed in future to supervise midwives shall have had adequate experience in the practice of midwifery. In order that an inspector of midwives should be regarded as the counsellor and friend rather than a relentless critic the persons appointed should not only possess the necessary professional qualifications but also the essential qualities of sympathy and tact. The title of inspector of midwives will be superseded by that of supervisor of midwives which is that used in the regulations. The regulation prescribe qualifications for a medical supervisor and a non-medical supervisor and it is within the discretion of each authority to appoint either one or the other or both. In large areas it appears to the Minister desirable to appoint a medical supervisor acting under the direction of the medical officer of health to exercise general supervision over the

¹ Statutory Rule and Order No. 1937 No. 294. The 311th of the Qualifications of Supervisors Regulations 1937 dated April 29th 1937.

midwives practising in the area, and non medical supervisors to work under the instructions of the medical supervisor and perform the routine duties of supervision

A medical supervisor is defined as a registered medical practitioner who has had at least three years' experience in the practice of his profession, and who (1) is registered as the holder of a diploma in sanitary science, public health, or State medicine, (2) has held the appointment of resident medical officer in a maternity department for a period of not less than six months, and (3) within a period of two years before his first appointment as a medical supervisor under the provisions of these regulations had had not less than one year's continuous experience in some branch of obstetric work. The Minister may dispense with any of the requirements of these regulations in any case in which it appears to him desirable so to do, on such terms and conditions as he thinks fit. The Minister appreciates that at the outset it may be difficult in some cases to secure medical supervisors who possess all these qualifications and if necessary he will be prepared to consider the question of using his dispensing power. He points out, however, that the words "some branch of obstetric work" have a wide range, and include the conduct of ante natal clinics, the duties of administrative officers in a maternity department, the investigation or treatment of puerperal fever, obstetric research, and so forth.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 1ST, 1937

Notifications—The following cases of infectious disease were notified during the week. Small pox, 0 scarlet fever, 1828, diphtheria, 1010, enteric fever, 26, pneumonia (primary or influenzal) 886, puerperal fever, 38, puerperal pyrexia, 99, cerebro-spinal fever, 30, acute poliomyelitis, 2, acute poli-encephalitis, 1, encephalitis lethargica, 5, dysentery 14, ophthalmia neonatorum, 102. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 7th was 3069 which included scarlet fever 799, diphtheria 866, measles 55, whooping-cough, 505, puerperal fever, 16 mothers (plus 11 babies), encephalitis lethargica 233, poliomyelitis 0. At St Margaret's Hospital there were 21 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths—In 123 great towns, including London, there was no death from small-pox or from enteric fever, 18 (0) from measles, 3 (0) from scarlet fever, 18 (4) from whooping-cough, 30 (3) from diphtheria, 48 (12) from diarrhoea and enteritis under two years, and 33 (3) from influenza. The figures in parentheses are those for London itself.

Five deaths from diarrhoea and enteritis under two years were reported from Liverpool, and 3 each from Manchester and Newcastle upon Tyne. Birmingham had 5 deaths from measles. Sheffield and Bradford each reported 3 fatal cases of diphtheria.

The number of stillbirths notified during the week was 284 (corresponding to a rate of 41 per 1000 total births), including 40 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg Capts J H Burdett to *Pembroke* for R N Hosp, Chatham, and J D Danson to *Victory* for R N Hosp, Haslar.

Surg Lt Comdrs J B Patrick to *President* for course, and C D D de Labilliere to *Pembroke* for R N B.

Surg Lts G C Denny to *Excellent*, W B Taylor to *President* for course, J G Vincent Smith to *Pembroke* for R M Infirmary, Chatham, I C Macdonald to *Pembroke* for R N B, and D Simpson to *Victory* for R N Hosp, Haslar.

F B Gamblen and J B Knight entered as Surg Lts (D) for short service, and appointed to *Victory* for course of instruction at R N Hosp, Haslar.

The following have been appointed Admiralty Surgeons and Agents—

Mr J W Ross (Darlington) for Darlington, Mr T C Gipson (Pinhoe Exeter) for Exeter, and Mr R Anderson (Helensburgh) for Helensburgh.

ROYAL NAVAL VOLUNTEER RESERVE

Surg Lt Comdr (D) G P Monk placed on Retd List
Surg Sub Lt R F Hand promoted to Surg Lt

ROYAL ARMY MEDICAL CORPS

Cpts A McMillan and W G S Foster to be Majs

Senior Medical Officer, Northern Rhodesia, Dr A A Cameron Medical Officer, Malaya and Surg Lt S R G Pumm, Medical Radiologist, Colonial Hospital, Port of Spain, Trinidad.

OBITUARY

BENNETT MAY C.B.E. FRCS Eng

EMERITUS PROFESSOR OF SURGERY UNIVERSITY OF BIRMINGHAM

His death occurred on May 3rd of Mr Bennett May emeritus professor of surgery in the University of Birmingham and one of the oldest members of the medical profession having reached the advanced age of 82. He died at his house in Edgbaston.

Prof May was the son of Benjamin May an official of the Inland Revenue and was educated at Sydenham College before proceeding to the University of Edinburgh for his medical education. He graduated as M.B. B.S. Lond. in 1875 and took the FRCS Eng. in the following year. He then became resident surgical officer at the Birmingham General Hospital at the termination of which appointment he became assistant surgeon to the Queen's Hospital Birmingham. His association with the University of Birmingham then Mason College began as a demonstrator in anatomy but his surgical work soon brought him a large consulting practice while he was invited to fulfil important appointments outside Birmingham such as surgeon to the Smallwood Hospital Redditch the Guest Hospital Dudley and the Tamworth Hospital. He was appointed demonstrator of operative surgery at Mason College and on the establishment of the University of Birmingham became professor of surgery in the University. He made now some important clinical contributions to medical literature writing in the *British Medical Journal* on the ligature of arterial trunks and to these columns valuable clinical notes among others a description of distal ligature of the common carotid and axillary arteries for aneurysm and one for the excision of a tumour of the cerebellum. In 1897 he delivered the Ingley lectures on the operative treatment of cancer of the breast the lectures being afterwards published in volume form. During the war despite his seniority he gave outstanding service at the Rubery Hospital.

Prof May was a widower and leaves no family. During the last years of his long life he was invalided by arthritis.

Sir Gilbert Barling sends the following tribute to Prof May's work and his personality: Bennett May commenced his medical studies as long ago as 1864 at the Sydenham College which was attached to the General Hospital Birmingham. In 1870 he was appointed to the valuable post of resident surgical officer with the supervision of all the surgical beds a position which he filled for three years and which formed the foundation of all his future success. He came to the practice of his profession in what may be called the transitional period when later a early teaching began to have its influence and at a time when laudable pus was almost regarded as a compliment to the surgeon and when all surgical operations were approached with an anxiety difficult to appreciate now for the threat of bad sepsis and even hospital gangrene was always present. And no wonder when amongst other detrimental conditions the surgeon was generally garbed in an old coat soiled with blood or even pus. May unlike his older predecessors was guided in his work by Lister's teaching that is he adopted the antiseptic system but hardly the minutiae of asepsis. To his disappointment he failed to secure a post as assistant surgeon to the General Hospital but found his opportunity at the Queen's Hospital when he was elected surgeon in 1881 and here he soon showed his worth. Rather a slow operator he was most pains-

taking and thorough his opinions were very reliable and he gave confidence to members of the profession who sought his advice in consultation. He taught anatomy at Queen's College and eventually became professor of surgery in Mason College and the University of Birmingham where I was his co-professor and I more than ever learnt to appreciate him as an excellent colleague and a very honourable man. He was at times a little eccentric in his mannerisms and students did not fail to exploit these but despite peculiarities he acquired the respect indeed the affectionate regard of those he taught.

During the war I had special reason to be grateful to him. In 1915 I organised two war hospitals in Birmingham and eventually these provided nearly 2000 beds. At that time it was not easy to secure an adequate surgical staff as nearly all the general surgeons in Birmingham were either on service abroad or attached to the 1st Southern T. Hospital. May had entirely given up practice and was then 70 years of age but at my request he took charge of a large section of beds and simply devoted himself to looking after them. For his services he was given the C.B.E. In his later years he was greatly crippled by arthritis indeed he was bedridden during the last five years this and his increasing deafness cut him off from his friends and he became very solitary. His death came as a real relief from distress he will long be remembered with affection.

SIR GEORGE WASHINGTON BADGEROW
C.V.O. C.M.G. MD Toronto F.R.C.S. Edin

The sudden death occurred on Sunday last of Sir George Badgerow a laryngologist equally well known in this country and in his native country of Canada. He was born in 1872 the son of Mr Harrington Badgerow of Toronto and was educated at Upper Canada College and the University of Toronto. He received his medical training partly at the Toronto General Hospital and partly at the University of Edinburgh and he was also a student at the Middlesex and University College Hospitals. He took the English double qualification in 1903 and two years later graduated as M.B. Toronto with honours proceeding to the M.D. degree in 1909 and taking the diploma of F.R.C.S. Edin in 1910. He early decided to specialise in diseases of the throat nose and ear and became chief clinical assistant in the department at University College Hospital. He then acted as clinical assistant and registrar at the Throat Hospital Golden Square becoming later resident medical officer posts which he held from 1903-08. He made during this period and later practical contributions to the literature of his subject describing in our

Photograph by E. and J. Fry

SIR GEORGE BADGEROW

columns several ingenious appliances useful in operative treatment, while he wrote in the *Practitioner* and also in *The Lancet* on the types of pharyngeal suppuration and on the general relation of diseases of the throat, nose, and ear to constitutional disease. He was appointed surgeon to the Golden Square Hospital and acted also as dean. He did fine service during the war as lieutenant colonel in the Canadian Army Medical Corps, both in the field and in institutional positions. He was mentioned twice in dispatches and at the conclusion of hostilities received the C M G. He was consulting surgeon to the Ontario Military Hospital, Orpington, to the Duchess of Connaught Red Cross Hospital, Cliveden, the King's Canadian Hospital, Bushey, and the Officers' (Daughters of the Empire) Hospital. He was a member of the Imperial War Graves Commission. In 1928 he was knighted and in 1930 was appointed C V O.

Sir George Badgerow was active in many provinces of his speciality. He was honorary surgeon for the diseases of the throat, nose, and ear to the Royal Normal College for the Blind, to the Livingstone Hospital, Dartford, and to the Warehouse Clerks and Drapers' Schools, Purley; he was a member of the Education Committee, L C C., of the Residential Open Air School in Bushey Park, and consulting surgeon to the Reedham Orphanage. It will be readily understood how well known he was in his profession as well as to all Canadians resident in or visiting England. He married Maud, daughter of Mr Herbert Oxley, who died recently, and leaves a son and a daughter. His death was tragically sudden; he collapsed in a taxi cab and was found unconscious at Waterloo Station. Conveyed to St. Thomas' Hospital he was found to be dead. He was 64 years of age.

CORRESPONDENCE

CONTINUOUS VENOUS HUM IN CIRRHOSIS OF THE LIVER

To the Editor of THE LANCET

SIR,—In your issue of May 8th Dr J L Bates records an interesting case of continuous venous hum in cirrhosis of the liver, the exact cause of which has not yet been confirmed at autopsy.

Some years ago I had under my care at the Sheffield Royal Hospital a case of cirrhosis of the liver with a somewhat similar localised venous hum. In my case it was possible to correlate the physical signs in life with the findings at autopsy. The loud and continuous venous hum in the earlier stages (1916) extended over the xiphisternum up to the level of the third costal cartilage with an area of maximum intensity over the former. Five years later (1921), when the ascites had all disappeared, the sound was sharply circumscribed to an area covered by a half-crown at the right of the sternum opposite about the sixth chondrosternal junction. At autopsy in 1924 there was a monolobular cirrhosis. The left portal vein was much dilated and communicated by a circuitous course through the round and falciform ligaments with the right internal mammary vein, which showed marked varicose dilatations. As this vessel was lying immediately under the place where the venous bruit was of maximum intensity, it seemed, on these grounds alone, to be the most likely source of the sound, and this view was supported by the sudden variations in diameter of its lumen, from narrow to wide, thus providing the requisite physical conditions which Dr Bates mentions—namely, “the passage of blood through a constricted lumen into a relatively dilated channel.”

An almost exactly similar condition was found in a case of Ogle's, quoted in Rolleston's text book (1912 edition), and apparently others of a somewhat similar kind to that described in Dr Bates's interesting record have been added in the later edition, to which I have not had an opportunity of referring. An account of my case, during life, was published in the *British Medical Journal* for April 15th, 1922.

I am, Sir, yours faithfully,

ARTHUR J HALL

PERNICIOUS ANÆMIA IN AN INFANT

To the Editor of THE LANCET

SIR,—Dr Smallwood's letter, in which he questions the correctness of the diagnosis of pernicious anæmia in the infant whose case was recorded by Langmead

and Doniach in your issue of May 1st, does not mention whether any of his cases of acute or sub-acute hæmolytic anæmia showed achlorhydria following injection of histamine. Of the previously recorded cases of pernicious anæmia in infants, few, if any, have fulfilled all the postulates required in the diagnosis of this disease. The case recorded by Langmead and Doniach fulfils all of them. Should the infant, at a later date, be able to thrive without liver therapy, it could reasonably be maintained that the syndrome had been caused by a temporary cessation of ability either to elaborate, or else to absorb the antipernicious anæmia factor. An analogous situation may arise in colic disease. The criteria of the diagnosis of pernicious anæmia, quoted by Langmead and Doniach, could have with advantage suggested achlorhydria following histamine injection.

I am, Sir, yours faithfully,

London, W 1, May 7th

J C HAWKSLEY

PRURITUS ANI

To the Editor of THE LANCET

SIR,—In recent issues of your paper I read interesting references to this subject, and it seems obvious that the treatment of pruritus ani is still wrapped in obscurity. I wrote to *THE LANCET* in 1923 (Sept 29th, 1923, p 678) recording the treatment which had been successful in my own case many years before. I then consulted Sir Charles (then Mr) Gordon Watson who held the view that the cause of this trouble lies in the papillæ of Morgagni, which situated at the anorectal junction, are absent in the majority yet present in a considerable proportion of individuals. They are normally small white glistening papillæ, pyramidal or triangular, with the apices directed upwards and inwards towards the lumen of the gut. They vary from one to six, and when hypertrophied resemble in size and shape the writing end of an ordinary lead pencil, when much hypertrophied they may be felt as small shotty nodules. In some cases one finds small fibrous branched papillæ as well, and I think it is advisable to destroy these also as they may possibly be an additional source of irritation. In my own case, Sir Charles Gordon Watson destroyed these hypertrophied papillæ with the electric cautery. This was done without even a local analgesic and was not very painful. The itching, which had become unbearable, disappeared.

¹ Parsons L G and Hawksley J C (1933) *Arch Dis Child* 8 117

at once like magic and I remained absolutely free for about five years. There was then a slight return occasionally but carbolic vaseline kept it in check. Later on as the pruritus had again become rather troublesome I was examined by a surgeon having first told him what he would probably find. He destroyed five or six papillae with instantaneous results and has since treated four similar cases with equally good effects. The reappearance of a papilla is in my case always attended by a return of the pruritus and discharge of irritating mucus which rapidly causes the skin to inflame.

I would add now that I have found that repeated cauterisations of the papillae of Morgagni deprive one of the sensitive area which gives warning of the presence of a stool at the anal orifice and occasionally if one had diarrhoea an accident was likely to occur. This is of course one of the results which is apt to follow Whitehead operation for piles or prolapse of the rectum.

I am, Sir, yours faithfully

FREE MILK AND CHEAP MILK

To the Editor of THE LANCET

SIR—Following the report of the Advisory Committee on Nutrition the Ministry of Health last month circulated maternity and child welfare authorities asking them to review their arrangements for the supply of milk and other foods to mothers and young children. May we comment on some of the issues involved?

In many areas pregnant or nursing mothers and children under school age cannot obtain free milk unless the family income fall beneath a very low level. We know of authorities where the income (after deduction of rent) for a family of five must be as low as 25s or even 22s 6d a week before free milk is granted. But the circular in urging that scales should be so framed as not to render it difficult for mothers to take advantage of the authorities' arrangements does not itself suggest any basis on which this should be done. Such a basis might be found in the British Medical Association's estimate of the minimum costs of satisfying food requirements as revised to conform with the milk recommendations of the Advisory Committee on Nutrition. If however the Minister feels that he cannot accept these estimates we suggest that he should ask the Advisory Committee itself to draw up for the guidance of local authorities a scale based on the present knowledge of food requirements. Estimates for necessities other than food such as have been used in the various social surveys could be added and the scale adjusted to changes in prices from time to time and place to place.

The report of the Advisory Committee indicates that on health grounds milk (or its equivalent in other protective foods) is necessary for all pregnant and nursing mothers and young children. However under most local authorities even after a stringent income test has been satisfied milk and other foods are only supplied free if clinical symptoms are discovered showing the need for additional nourishment. Should not local authorities be asked to provide free milk wherever the income available for expenditure on food is insufficient and thereby anticipate the dangers of undernourishment before health is actually impaired?

The Minister's circular which seeks to implement the report of the Advisory Committee is valuable in

encouraging local authorities to remove some of their restrictions; but further measures will undoubtedly be required if we are to secure that largely neglected consumption of safe milk by mothers, children and adolescents which the Committee states would do more than anything else to improve the health development and resistance to disease of the rising generation.

The onus for extending the provision of milk remains on the local authorities who will have to pay the whole cost of such an extension out of the rates. It is true that the poorer authorities have benefited by the recent revision of the Milk Grant but such relief is required for many purposes including the reduction of rates raised to unprecedented height by years of severe unemployment.

Measures on an extensive scale will be needed if the hope of the Advisory Committee that a supply of safe milk to the amount we have recommended is brought within the purchasing power of the poorest is to be fulfilled. These amounts are 2 pints a day for expectant and nursing mothers and from 1 to 2 pints a day for each child. With milk at 3d a pint a family in which there were three children taking say 13 pints a day and a mother taking 2 pints would have a bill of 13s 3d a week. Such an expenditure is as recent surveys show quite beyond the means of most working class families with young children.

At present about one third of the milk produced is sold for manufacture at an average subsidised price of 5d a gallon whereas it is only available for liquid consumption at a price which puts a sufficient quantity for health beyond the reach of many families. It is understood that the Government are considering a scheme for extending the provision of cheap milk to mothers and children under school age. We very much hope that a result of the report of the Advisory Committee will be its early initiation.

We are, Sir, yours faithfully

PRISONERS AND CAPTIVES

To the Editor of THE LANCET

SIR—Despite your mental hospital correspondents who so vigorously championed the statutory hospital against Taddygaddy in your issue of May 1st is there not a subtle difference? Is it perhaps a matter of the limelight focused on the voluntary institutions owing to the continual fight for funds? The public develops an almost parental feeling of responsibility; not only does it support financially, it protects, cherishes even exiles. Statutory hospital still confronts the locked door the inferiority stigma has not yet vanished. The governing bodies are criticised with a difference; members of county or borough council must be rationed out over the word to be done and the hospital committee may perhaps be the Cinderella that gets the beatings. At any rate there seems to be less opportunity for detailed intercourse, informal knowledge, personal contact; they all have too much to do.

At a recent opening of a municipal hospital the equipment shown was superb but where were the local doctors and their wives and their friends? It was a different crowd; it nearly always is. If

Taddygaddy and your correspondent are both right surely an urgent and immediate task ahead is to find a way of amalgamating "atmospherics" or at least of demonstrating that no real difference need exist

I am, Sir, yours faithfully,

ESTHER CARLING

Berks and Bucks Joint Sanatorium, Oxon, May 6th

To the Editor of THE LANCET

SIR,—Taddygaddy fain would raise a storm Will there be pennies from Heaven? Authority, in spite of all the gossips, is not too mean a deity

There is, of course, much of truth in Taddygaddy, much to welcome Nevertheless, whensoever we seek to preach thus freedom, ought we not first to ask with Nietzsche "Freedom for what?"

I am, Sir, yours faithfully,

Birmingham, May 10th

H FREIZE STEPHENS

INSULIN SHOCK TREATMENT OF SCHIZOPHRENIA

To the Editor of THE LANCET

SIR,—In the excellent account of insulin shock in schizophrenia given by James, Freudenberg, and Cannon in your last issue, the question of depth of coma arises Coma is rightly defined as a period of unconsciousness, but the differentiation of depths of coma is rather at variance with that set out in Dr I G H Wilson's report and so may lead to confusion James and his collaborators define coma as "unconsciousness," deep coma being characterised by loss of corneal and plantar reflexes and also by hypotonus Dr Wilson describes "light coma," coma with restlessness and all reflexes present, coma proper, in which hypo or hyper tonus is seen and in which the corneal reflex is absent, "deep coma," in which the pupillary light reflex is lost I feel that this difference should be emphasised, as any attempt to prolong this latter form of deep coma for the 1½ hours permissible for the deep coma of James, Freudenberg, and Cannon would undoubtedly be disastrous

The "coma" mentioned in the very brief note on method in my report on cases, being unqualified, simply means "period of unconsciousness" When this is 2½ hours it is usual to find, with proper dosage of insulin, that 1 hour is spent in light coma and 1½ in coma proper I cannot agree that hypertonus in general extension is an imperative indication for interruption and have frequently seen this and allowed hypoglycæmia to continue for the usual length of time some cases have shown this daily

I am, Sir, yours faithfully,

LEONARD W RUSSELL

St Bernard's Hospital Southall May 10th

EAST HAM MEMORIAL HOSPITAL—This hospital is now free from debt for the first time in its history In 1935 it had a deficit of £18 000, half of this sum was given by Lord Bethell the president and the other half by the public A new children's ward is required and Lord Bethell has offered to meet half its cost in commemoration of the Coronation

NATIONAL HOSPITAL FOR NERVOUS DISEASES—Princess Alice Countess of Athlone has laid the foundation stone of the extensions to this hospital which have been made possible by a grant from the Rockefeller Trust The extensions will be devoted to the work of the clinical research unit, while facilities for neurosurgical work and some small wards for paying patients will also be provided

CORONATION HONOURS

THE list of honours bestowed by the King at his Coronation contains the following names of members of the medical profession —

Baron

The Rt Hon Christopher Addison, F R C S
First Minister of Health (1919-21)

Baronet

Sir Cuthbert Wallace, K C M G, C B, M B
President of the Royal College of Surgeons

K C B

Edward Mellanby, F R C P, F R S
Secretary of the Medical Research Council

K C V O

Sir John Atkins, K C M G, F R C S
Physician in Ordinary to the Duke of Connaught
George Frederic Stall, F R C P
Consulting physician for diseases of children, King College Hospital

K B E (Military)

Air Vice Marshal Alfred Wilham Iredell, C B
M R C S, K H P
Director of medical services, Air Ministry

K B E (Civil)

The Hon John Richards Harris, M D
Minister of Public Health, Victoria

Knights Bachelor

Arthur Edwin Horn, C M G, M R C P
Consulting physician to the Colonial Office
Arthur Frederick Hurst, F R C P
Senior physician to Guy's Hospital
Harold Beckwith Whitehouse, F R C S
Professor of midwifery University of Birmingham

C B (Military)

Surgeon Rear Admiral G L Buckenridge, O B E,
M R C S, K H S
Major General W H Hamilton, C I E, C B E, D S O,

THE LANCET 100 YEARS AGO

May 20th 1837 p. 315

From the report of a paper on malignant diseases of the skin of the face read by Mr. CASPAR HAWKINS at a meeting of the Royal Medical and Chirurgical Society held on May 9th 1837—Dr. BRIGHT Resident

The term "malignant disease" however having been employed in a very vague and ill-defined manner the author commences by stating that he restricts the term malignant to such diseases as essentially possess a new structure capable of exerting a poisonous influence in one or more of these several degrees: 1st upon the neighbouring textures which are converted into a substance exactly similar or at least analogous to that of the new formation; 2ndly Upon the absorbent system so that the neighbouring gland become enlarged into a tumour like that originally deposited or 3rdly Upon the whole constitution, so that the poisonous secretions of the newly formed part gain access to the circulating fluids and tubercles of various forms but of the same or an analogous character become developed in some distant organs or textures which have no direct communication except through the blood with the parts in which the new structure was first formed

* * Our centenary extract this week contains two historic medical names Richard Bright who gave his name to Bright's disease was the first to connect albumin in the urine with dropsy no one previous having suspected the kidney to be the organ implicated

Caspar Hawkins an eminent man himself is often confused with his grandfather Sir Caspar Hawkins. The name Caspar had come down in the family from the sixteenth century. Sir Caspar was sergeant surgeon to King George II and King George III and his portrait by Hogarth is in the Royal College of Surgeons of England. His grandson whose name appears above was like Sir Caspar on the staff of St. George's Hospital. As a student he worked under Edward Home and Benjamin Brodie. He taught anatomy in association with Charles Bell in the Windmill street school and he was president of the College of Surgeons of England in 1842 and again in 1891 being one of the last presidents to hold office twice after an interval—E. L.

MEDICAL NEWS

University of Cambridge

The board of research studies has approved Prof C G Okell, F.R.C.P., for the degree of doctor of science

Royal College of Physicians of Edinburgh

A meeting of the college was held on May 4th with Dr W T Ritchie, the president, in the chair. Dr Douglas James Campbell (Grimsby) was introduced and took his seat as a fellow. Dr George Abeyesingha, Weera Wickramasuriya (Ceylon) was elected to the fellowship. The Freeland Barbour fellowship was awarded to Mr Walter Tebrich, B.Sc.

Honour for Sir Patrick Laidlaw

The faculty of medicine of the University of Toronto has awarded the Charles Mickle fellowship to Sir Patrick Laidlaw, F.R.S., of the National Institute for Medical Research, London, for his contributions to practical medical research.

Royal Society of Arts

On Wednesday, May 26th, at 8.15 p.m., Prof H D Kay, D.Sc., director of the National Institute for Research in Dairying of the University of Reading, will address this society on the biochemistry of milk secretion. Applications for tickets should be made to the secretary of the society, John-street, Adelphi, W.C.2

National Physical Laboratory

Prof W L Bragg, F.R.S., Langworthy professor of physics in the University of Manchester, has been appointed director of the National Physical Laboratory. He will take up his duties in the autumn.

Science and Peace

One of the commissions of this year's National Peace Congress, which meets in London from May 28th to 31st, is concerned with the contribution of science and medicine to peace. The chairman is Prof S Chapman, F.R.S., of the Imperial College of Science, and the introductory address will be given by Prof P M S Blackett. Particulars may be had from the National Peace Council, 39, Victoria street, London, S.W.1

International Rheumatism Congress

The annual international symposium organised by the Ligue Française contre le Rhumatisme will be held this year in Paris on Oct. 9th under the presidency of Prof Laignel Lavastine on radiotherapy in rheumatism. In the morning a clinical meeting will be held at Prof M Loeper's medical Clinic, Hôpital Saint-Antoine. At 3 p.m. the congress will meet at the Faculty of Medicine when Coste (Paris) will discuss radiotherapy, Piéry, Cluzat, and Milhaud (Lyons), emanotherapy, and Euzière and Castagne (Montpellier), the radio active action of thermal waters. Further information may be had from the offices of the Journée du Rhumatisme, 23, rue du Cherche Midi, Paris, VI.

Association of Registered Biophysical Assistants

At a meeting of the executive committee on April 15th it was agreed that this association, which was founded in 1932, should in future be known as the Society of Physiotherapists. The change of title is made desirable by the formation of the National Register of Medical Auxiliaries, in which the Roll of Biophysical Assistants is now incorporated. Membership of the Society of Physiotherapists will be limited to those termed physiotherapists in the National Register of Medical Auxiliary Services. The society is not an examining, qualifying, or registering body, its principal aim is to represent its members by making their work known to the medical profession and the public thereby promoting the expert administration of physical methods of treatment and the ultimate elimination of the unqualified from the field of physiotherapy. Applications for membership may be addressed to the hon. secretary at 159, Victoria street London, S.W.1

Lord Horder has been appointed a deputy lieutenant for Hampshire

Glasgow Royal Infirmary

As soon as space is available in the new premises in the Blind Asylum buildings, a fracture clinic is to be set up. Accommodation will be provided for both out patients and in patients with ten beds for men and ten for women.

International Leprosy Conference

The fourth International Leprosy Conference will be held at Cairo beginning on March 21st, 1938. This will be the first international conference to be arranged by the International Leprosy Association since its inauguration in 1931. Previous conferences were held at Berlin in 1897, at Bergen in 1909, and at Strasbourg in 1923. Further information may be had from the secretary, 131, Baker street, London, W.1

International Union against Tuberculosis

The Italian Fascist National Federation against Tuberculosis has placed at the disposal of the Union six scholarships each of the value of 2000 liras with board and lodging at the Carlo Forlanini Institute in Rome. The scholarships will be awarded to young physicians who are already familiar with tuberculosis problems and who wish to improve their knowledge of this branch of medicine. The kind of work undertaken at the institute will be arranged between the director of the institute and the candidate, and papers on the work must be submitted for publication in the first instance to the editor of the *Bulletin* of the International Union against Tuberculosis. The scholarships will be awarded at the next session of the executive committee which will meet in Lisbon in September. Applications should reach the secretariat of the Union, 66, Boulevard, St-Michel, Paris, by July 6th.

Research in Tropical Medicine

The Medical Research Council advised by their tropical medical research committee which was appointed after consultation with the Colonial Office (*THE LANCET*, 1936, I, 558) have decided to offer three junior fellowships to qualified medical men who wish to receive training for research work in tropical medicine. Preference will be given to candidates who have already had preliminary experience of methods of research in some branch of medical science. Subject to satisfactory reports, the fellowships will be tenable for three years. The first year will be spent at a school of tropical medicine, the second in doing research in the same or some other institution at home, and the third largely in work under direction at some centre in the tropics. The stipend will be at the rates of £300, £400 and £500 per annum in the successive years, with an additional allowance during service abroad and necessary expenses. In three years' time, at least one senior fellowship will be available for candidates who have held the junior fellowships mentioned above. This will be awarded for a further period of three years, carrying stipend at the rate of £600-£750 per annum with an additional allowance during service abroad and expenses. The time will be spent mainly in research work in the tropics. The council are also prepared to consider immediate applications for senior fellowships from candidates who have had adequate experience in research work, whether already specially trained in tropical medicine or not.

The council intend to establish in due course, as suitable investigators become available as the result of the fellowships scheme, permanent and pensionable appointments for research work in tropical medicine, including senior posts. Members of this research staff will work partly in the tropics and partly in institutions at home to which they will be attached. The exact terms of service are still undecided but they will be not less favourable than those which apply to other Government appointments at home or overseas for men of similar professional standing. Inquiries may be addressed to the secretary of the tropical Medical Research Committee, 38, Old Queen street, London, S.W.1, to whom applications should be sent not later than June 15th.

NOTES, COMMENTS AND ABSTRACTS

A COMMERCIAL ART CENTRE

A MEETING for the inauguration of a commercial art centre was held recently at the Royal Society of Arts and some of our readers may be interested in the project. The intention is to establish in London a centre where specimens of the work of practising commercial artists can be displayed. Those behind the scheme find that manufacturers, advertisers and their agents find a difficulty in choosing the right artist for the advancement of a publicity scheme. It is difficult both to obtain a sufficient range of a particular artist's work at short notice and to discover new talent. The artist who is not working to a particular commission experiences difficulty in keeping touch with the general market, and only a few artists possess so many specimens of their work that they are able to keep possible buyers adequately informed. The establishment of a centre where an up-to-date range of the work of available artists could be inspected would solve the difficulties. The proposed commercial art centre would be situated in London and supported by the Society of Industrial Artists and the Incorporated Society of Artists in Commerce. It is not intended that the centre should act as an agency for the sale of work. Its effect would be to place buyers in direct touch with artists or their agents. The scheme has been worked out in some detail both financially and otherwise and has received promises of support from responsible sources. Those interested in the movement should communicate with the secretary of the organising committee, Commercial Art Centre, 4 Bedford-square, London W.C.

A DOYEN OF MICROCHEMISTRY

THE celebration by Prof. Hans Molisch of his eightieth birthday has been made the occasion for the issue of a special commemorative number of the journal *Mikrochemie* in view of the valuable contributions which Prof. Molisch has made to microchemistry. The number contains 47 papers by 45 different authors, many of whom have been his pupils. The contributions cover a very wide range of topics and vary considerably in size, one of the longest being by Prof. H. Fischer on the constitution of chlorophyll, which covers some 30 odd pages. The subjects dealt with are by no means exclusively botanical and cover all branches of inorganic and organic analysis as applied to foodstuffs, drugs, pharmaceutical products and the detection of traces of carotene in blood.

THE MAXAID HEARING AID

TWO so-called pocket model hearing aids with valve-amplification have recently been produced by the Ico-Scott Company of 62 High Holborn, London W.C.1. In both the apparatus is incorporated in a small unusually flat case measuring 6½ by 5½ by 1½ in. A small self-sitting ear piece may be used or the more usual disc-shaped one held by a light spring band. The low-tension current is supplied by two dry cells with a normal life of 25 to 30 working hours or an accumulator may be substituted at an extra cost of 7s. 6d.; the high-tension current is provided by a small dry battery stated to give several months' service. Both forms of dry cell are of well-known makes easily obtainable. The high-tension one costing 3s. 9d. and the low-tension 3d. each, so that upkeep is inexpensive. A volume-control is provided and also a tone-control adjusted by means of a set screw inside the case. The latter is intended to be set to suit the wearer's individual hearing and then to be left undisturbed. It is a useful feature which enables the instrument to be adapted to cases with loss of either

high or low tones. Model 52 P.L. employs two stages of amplification and costs 12 guineas while model 53 P.L.C. costing 10 guineas, has three stages and in addition a crystal microphone. This latter model, which we have examined is very sensitive and at the same time free from background noise. The makers suggest that the instrument may be kept in a man's pocket during use, but this is hardly to be recommended. Although small it is rather too large for the ordinary pocket microphone is not then in the best position for receiving sounds and friction against the clothes sets up disturbing noises. Better results are obtained with the instrument on the table or on the knee. It is a very neat and efficient apparatus.

PROPAGANDA AGAINST VENEREAL DISEASE

A VALIANT attempt to dispel the fog of ignorance and misconception still surrounding the subject of venereal disease in the public mind has been made by Mr. Carl Warren¹ who urges that these diseases if jointly attacked by doctors, public health authorities and the public could be virtually prevented or cured. Without intelligent co-operation from the patient the medical profession is hopelessly handicapped, hence the importance of teaching the public the facts and fallacies concerning syphilis and gonorrhoea and the value of such a book as this. The Scandinavian countries have already achieved a large measure of success in reducing the incidence of venereal disease, and there seems no reason why America and this country should not follow suit provided public enlightenment kept pace with medical knowledge and organisation. The book is written simply and accurately. The author obviously has no very high opinion of the existing standard of sexual ethics in America. Although the statistics are drawn almost entirely from American sources the book could be read with profit by young persons and particularly by those concerned with education in any country.

A HOSPITAL DIARY

Messrs. Fredk. Aldridge, 31 Paternoster-row, L.C.4 issue annually a diary particularly directed to the needs of the hospital world. The issue for 1937 is edited by Mr. F. P. Carroll. The diary contains in addition informative articles on law and engineering which should prove particularly helpful to the efficient management of a hospital. Ample space is left for entries in the body of the diary and a thumb index facilitates reference. A comprehensive buyers' guide arranged alphabetically under the names of the articles is included in the diary. The price of the diary is 5s. 6d.

CONTRACEPTION: PRINCIPLES AND TECHNIQUE

PROBABLY nurses, health visitors and midwives receive more inquiries about contraceptive principles and methods than any other member of the community and a book² written essentially for their instruction deserves attention. Dr. Griffith writes well if somewhat dogmatically. He discusses the advantages both to the individual and the State of the proper spacing of families and emphasises the urgent need to check dysgenic breeding. He relates the various devices, both past and present, used for limiting families, including abortion, intra-uterine devices, coitus interruptus, and sexual abstinence, and draws the conclusion that the soundest method is scientific birth control. As a member of the medical sub-committee of the National Birth Control Association he can speak with some authority on matters of

¹ *Mikrochemie*, Festschrift zum 80. Geburtstag von Hofrat Prof. Dr. Hans Molisch, Vienna: Emil Heilm and Co. 1936. Pp. 434. 3s. 6d.

² On Your G and I, by Carl Warren, B.A., B.S., M.D., Foreword by M. J. E. P. M.D., New York: Emerson B. A. Inc. 1937. Pp. 160. 5s.
³ Voluntary Parenthood, by F. W. E. Griffith, M.B.E.S., L.R.C.P., London: Heinemann, 1937. Pp. 141. 3s.

contraception and he describes briefly those which have best stood the test of clinical and laboratory investigation. Sexual education and ethics, the meaning of marriage, and the importance of family stability are given considerable space, but the chapters on genetics, the biology of cell division, and the internal secretions are somewhat sketchy. A few unfortunate inaccuracies have crept in on p. 103, for example, the author speaks of the ovarian follicular hormone (or folliculin) when he obviously means the corpus luteum hormone (progesterin or progesterone). An index, a list of voluntary and municipal clinics giving birth control advice, the Ministry of Health's memoranda on birth control, and a short bibliography are appended.

THE "BREVIS" IONIZER

At the present time zinc ionisation is being largely used in the treatment of hay-fever and similar nasal affections. The Victoria Electric Plant Company, of Spenser street, Westminster, have produced a convenient instrument for supplying the necessary electric current. It consists of a polished wood case measuring about 18 by 7½ by 7 in., containing an "Ever Ready" dry battery delivering a current of 30 volts, together with an instrument-board on which is mounted a voltmeter actuated by a push switch for checking the output from the battery, and a milliammeter with a red line at the 3 milli-ampere mark. The rheostat to regulate the strength of current is controlled by two rotating knobs giving a fine and very even adjustment. There is also a space for storing the necessary leads and terminals. The price is 10 guineas, and a somewhat smaller model without a cover to the instrument panel is supplied at 8 guineas. It is a well-made and portable machine for the application of ionisation for any purpose.

CORRIGENDUM.—Insulin Shock Treatment of Schizophrenia. In the article by James, Freudenberg, and Cannon, published in our last issue, the word subcutaneous in the second line on p. 1102 under the cross heading Phases of the Treatment should read *intramuscular*.

ADDRESSES AND ORIGINAL ARTICLES

THE BIPP METHOD OF TREATMENT OF ACUTE OSTEITIS*

BY JAMES H SAINT JLD Durl. FRCS Eng
F.A.C.SCONSULTING SURGEON TO THE THOMAS KNIGHT MEMORIAL
HOSPITAL, BLYTH, AND SENIOR SURGICAL REGISTRAR AT THE
ROYAL VICTORIA HOSPITAL, NEWCASTLE-ON-TYNE

ALTHOUGH acute osteitis may be said to be relatively infrequent in comparison with the more common acute surgical conditions its seriousness must necessarily render this disease one of great importance. Wakeley (1932) quoted figures from hospitals in the British Isles to show that there was a gradual lowering of its incidence in the last decade as compared with that of the first decade of the century. However the latest figures from the Registrar General's office show that whereas in 1931 there were 403 deaths from this disease † in 1935 the number was 447. Other figures from the same source indicate that the death rate was a little higher in 1926-30 than it was during 1921-25 but that since 1930 there has been no significant change. Thus it seems that the last 15 years have not brought forth evidence to support the comforting belief in a continued though gradual disappearance of this disease.

Some idea of how serious acute osteitis is may be had from Table I which shows the fatality rates in recently published series of cases.

TABLE I
Fatality rates in Acute Osteitis

Author	Percentage of deaths.
Eric Lloyd (1928)	32.5
Pyrah and Pain (1932)	27.1
John Fraser (1934)	24.0
Ogilvie (1928)	19.0
Gwynne Williams (1932)	15.9
Alex Althoff (1928)	11.8
Holman (1934)	9

It is seen that in some instances one patient out of every three or four died a fact which cannot be regarded with complacency. Mortality alone however is not the only feature of acute osteitis that makes it a disease of serious import for amongst those who recover may be seen deformity and interference with function of greater or less degree and these patients often suffer from recurrent attacks either in the bone first affected or in others at intervals during a long life. Thus acute osteitis often leaves in its wake sequelae that may cause, if not actual chronic invalidism at least impairment of capacity for work and of enjoyment of life. Any method of treatment therefore that holds out hope of reducing its mortality and decreasing its morbidity deserves consideration and it is the belief that the BIPP (bismuth iodoform paraffin paste) method of treatment may accomplish these objects that is largely responsible for this contribution.

The term osteitis is used throughout as meaning the inflammation of any or all of the constituent parts of bone which are so intimately connected with

one another—namely the periosteum, osteum and medulla. In view of this nomenclature such terms as periostitis indicating inflammation of the periosteum and osteomyelitis (or myelitis) intended usually to infer inflammation of the marrow-containing medullary cavity become superfluous apart from possessing the disadvantage of tending to denote that they represent separate diseases.

The present article will consider only the typical form of acute osteitis found in young people where the blood stream is the channel of infection. No reference will be made to the more uncommon type due to the direct introduction of organisms into the bone as for example in a compound fracture.

Pathological and Clinical Aspects

Success in combating any acute infective disease depends upon two factors—first correct diagnosis of the condition in its earliest stages—i.e. before complications due to spread of the infection have developed and secondly the institution of a rational form of treatment based upon a proper conception of the pathology present. Acute osteitis is no exception to these general rules, and attention is drawn to certain of its pathological and clinical features which have an important bearing on these points.

PATHOGENESIS

Acute osteitis begins as a small, delimited focus of infection in the cancellous tissue of the metaphysis of one of the long bones, usually at the more actively growing end. The importance of realising this fact cannot be over-emphasised, for at this stage the focus can be completely removed this procedure constituting the rational treatment. From this focus the infection if not checked will spread to involve the periosteum, the surrounding soft tissues (giving rise to an acute cellulitis) and the medullary cavity. Thus it is seen that acute periostitis and acute osteomyelitis are not separate diseases but are only complications due to the spread of infection from the initial bony focus, the infection still being confined to the bone itself. Starr's hypothesis (1922) that the spread of infection commonly takes place towards the periphery resulting in early involvement of the periosteum and that infection of the medullary cavity occurs relatively late by way of the Haversian canals secondarily to involvement of the periosteum receives support in my own clinical experience for in my series of cases a subperiosteal abscess was often present while the medullary cavity was not yet involved.

A further feature of the pathology of acute osteitis is the relationship between the general and local infections. It is often stated that acute osteitis is a local manifestation of a systemic disease but this appears to be an incomplete representation of the true facts. It is accepted that the organisms reach the bone by way of the blood stream, this path of infection pre-supposing a septicaemia to be present before the bone becomes affected. Since this is so it must be admitted that the septicaemia must be a mild type since it gives rise to no symptom, the general symptoms which point to an infection of the blood stream only obtruding themselves upon the clinical picture after the development of the bony focus. Thus it seems reasonable to a sume that these symptoms are caused by a reinfection of the blood stream from this focus. It is suggested, therefore, that the sequence of events is as follows: (1) a mild

*Based on a Hunterian lecture delivered at the Royal College of Surgeons of England on Feb. 5th.
†The varieties of acute or description of disease included in this group by the Registrar-General are as follows: acute osteomyelitis, epiphyseal osteomyelitis or necrosis of bone, infective osteomyelitis, periostitis or necrosis of bone, septic or suppurative osteitis or osteomyelitis or epiphysitis and Brodie's abscess. If and where inquiry to be a description of one of the foregoing diseases.

form of septicæmia with slight or no symptoms (consequent upon some septic focus in the skin or mucous membrane), (2) a focus of infection developing in the metaphysis of one of the long bones (the condition then becoming one of acute osteitis), (3) severe blood stream infection (toxæmia or septicæmia in the early stages or pyæmia later) due to absorption of toxins or organisms from the bony focus. Hence to regard acute osteitis as "a local manifestation of a systemic disease" is to consider only the relationship between the bony focus of infection and the primary mild septicæmia and to omit to take into account the all important fact that the serious systemic infection seen in acute osteitis occurs *after* the development of the bony focus and *is consequent upon it*. This view of the pathological sequence of events is one that calls for removal of the bony focus at the earliest possible moment.

SYMPTOMS AND SIGNS

From what was said about success in combating an acute infective disease, it follows that the important clinical features to know about acute osteitis are those that will help to establish the diagnosis of this condition in its earliest stage. The clinical picture, only too easily diagnosed, of high temperature, delirium, and a red, hot, swollen limb, almost literally a bag of pus, indicative of the spread of infection to such an extent as to make it almost impossible to save life, should be regarded as a relic of the past when the early symptomatology and pathology were but little understood. It is true that the disease occurs in young subjects before the epiphyses have united, that the patient is usually of the hospital class, often undernourished, with evidence of some recent infection of skin or mucous membrane and with a history of a blow or fall, but with the exception of the first-mentioned all these features may be absent in a given case. It is therefore important to bear in mind that, as in other acute surgical conditions, the history may not be typical and that an atypical one must not be allowed to cast doubts upon the diagnosis. What, then, are the special features in the symptomatology which can be said to point unequivocally to the diagnosis of acute osteitis in its earliest stage? They may be considered under *general* and *local* and are as follows—

GENERAL

Inflammatory fever—Often starts with a rigor, especially in severe cases, with a temperature of 100°–105° F and of a continuous type.

Polymorphonuclear leucocytosis—This is always present except in cases where the virulence of the infection is so great as to overwhelm the resistance of the patient, it is important because it indicates the presence of a pyogenic infection.

LOCAL

Pain of sudden onset and intense, over the end of a long bone, it is worse at night and usually prevents the patient from sleeping for more than minutes at a time.

Tenderness—Where the pain is complained of, palpation will reveal a spot of exquisite tenderness.

This triad of *elevated temperature* with *pain* and *tenderness* over the end of a long bone found on clinical examination, associated with a *leucocytosis*, definitely establishes the diagnosis and should be impressed upon the minds of medical students and practitioners, so that no doubt will remain about the significance of these findings and so that any patient found suffering from them will be regarded as a surgical emergency.

Since the diagnosis appears simple, why is it that so many cases of acute osteitis are not seen by a

surgeon for several days after the onset of their illness? There is no doubt that the most prevalent cause of delay is the provisional diagnosis of acute rheumatic arthritis accompanied by the decision to await the result of giving salicylates. What are the reasons for this frequent error of diagnosis? They are to be found in the swelling (the so called "sympathetic effusion") and apparently painful movements of the adjacent joint, leading to inadequate examination. Insufficient attention is paid to other symptoms and signs which are present—namely, that the pain is not in the joint but only *near* it, that careful palpation will reveal an adjacent metaphysis to be exquisitely tender, and that a definite degree of passive movement of the joint is obtainable without pain such as would never be the case were the joint the seat of an acute rheumatic arthritis. Absent also will be the involvement of other joints and the peculiar sweating of the rheumatic patient. Two other conditions which may be mistaken for acute osteitis are acute infective arthritis and acute cellulitis, but these have the advantage of being such that a surgical opinion will be sought at once, so that no time will be lost. In the former, any attempt to obtain passive movement causes excruciating pain and such pain may be caused even by an attendant walking across the floor or by touching the bed, much less the affected extremity. Acute cellulitis near the ends of the long bones is so uncommon in the absence of underlying bone infection that it was made the subject of one of Rutherford Morison's many pertinent aphorisms, "Cellulitis in a young limb means osteitis." However, it should be remembered that cellulitis is a complication of osteitis and indicates that the infection has already spread through the periosteum into the surrounding soft tissues. There is one further observation that is of great use in the diagnosis of acute osteitis, and that is the absence of involvement of the lymph glands draining the area superficial to that where pain and tenderness are present, these are always the seat of a lymphadenitis in cases where the infection has begun in the soft tissues.

Actions of BIPP

Bismuth iodoform paraffin paste (Bipp) consists of bismuth subnitrate 1 part, and iodoform 2 parts, mixed with liquid paraffin in sufficient quantity to form a paste. The presence of the bismuth salt recalls the paste used by Emil Beck, but the addition of the iodoform results in a chemical action which gives Bipp its valuable properties. In the Pharmaceutical Codex the formula of Bipp is given as bismuth subnitrate 25 per cent, iodoform 50 per cent and liquid paraffin 25 per cent. One interesting feature of this formula lies in the fact that whereas iodoform is used ordinarily in strengths of 5–10 per cent, its incorporation into Bipp enables it to be used in a strength of no less than 50 per cent. The origin of Bipp dates back to the late war when, at the Northumberland War Hospital, Prof Rutherford Morison (1918) was experimenting, with the help of Mr W W Hunter, to find an ideal antiseptic—that is, one of such a strength as to inhibit the growth of organisms without doing tissue cell damage. At this time many of the men sent to this hospital had foul, discharging wounds necessitating frequent dressings, to the exhaustion of the nursing staff and to the agony of the patients themselves. After the institution of the Bipp method of treatment the scene changed dramatically, for these wounds ceased to be painful, dressings were only necessary at weekly or less frequent intervals, and the wards "were

full of cheerful men whose chief anxiety seemed to be to know when they could get up (Morrison 1922). This method of treatment was adopted widely for wounds and compound fractures both clean and infected, by the British Army authorities at home and abroad and was the means whereby thousands of limbs and lives were saved to say nothing of the relief from suffering which was achieved.

The chemical and bacteriological actions of Bipp were demonstrated by the work of Anderson Chambers and Goldsmith (1917) as a result of extensive experiments. They consider that the chief chemical reaction that takes place consists in the oxidation of the iodoform by oxygen derived from the air or from arterial blood and by the nitric acid formed by the hydrolysis of the bismuth salt. The result of this reaction is the continued liberation of small quantities of free iodine. They found that although organisms were still present in wounds treated by Bipp yet they were unable to proliferate freely and that the wounds healed as though they were surgically clean. It seems that the introduction of Bipp into a wound results in the liberation of nascent iodine thus forming a mild continuously acting antiseptic which acts as a deterrent to the growth of organisms but does no harm to the tissues. As illustrating this continuous chemical action of Bipp it is of interest that after the application of the paste to a wound iodine has been recovered daily in the urine for as long as three weeks.

At this juncture it might be well to draw attention to the fact that Bipp can act as a poison as disadvantage from which it was found to suffer in the early days of its use if large quantities were left in wounds. It is also dangerous to use it in the serous cavities on account of possible absorption of the iodoform. Except for occasional idiosyncrasy examples of which must be very rare and have never occurred in my extensive experience of Bipp there need be no fear of poisoning provided that the paste is used sparingly in the manner to be detailed later. Should poisoning occur it may be due to either the iodoform or the bismuth salt. Iodoform poisoning is usually seen within 24 hours of operation the symptoms being a high temperature—often 103 to 105 F—a rapid pulse, dilatation of the pupils a red tongue and sometimes the appearance of a bright scarlet rash. There may be no complaint from the patient. The pulse becomes more feeble and rapid and the patient may die delirious and of heart failure. Bismuth poisoning is a later manifestation the symptoms usually not appearing until four or five days after operation. The patient complains first of a sore mouth and on examination the breath is foul the gums are spongy and show a black line round the teeth due to the deposition of bismuth sulphide. In severe cases much salivation is present the black deposit may be seen on the tongue and cheeks as well as on the gums and ulceration is likely to occur the breath meanwhile becoming more and more foul; diarrhoea may ensue the temperature becomes raised a secondary anaemia develops and the patient a condition rapidly deteriorates. In either case the only hope lies in the immediate evacuation of the Bipp and while this may lead to relief in a case of bismuth poisoning patients with serious symptoms of iodoform poisoning often die in spite of this measure and any others that may be taken.

Method of Treatment

The principles which govern this method of treatment of acute osteitis may be outlined briefly as

consisting of (1) the complete removal of the infected bony focus (2) the disinfection of the resulting wound by Bipp in the manner to be described and (3) immobilisation of the affected part. It is considered that these measures will arrest the spread of infection if they have been carried out efficiently. With this object in view it is clearly important to realise that the disease begins as a small bony focus for this can be completely removed and that delay in diagnosis through leading to spread of the infection will render the operative treatment more prolonged and more extensive and may decrease materially the likelihood of complete removal of the infected tissue thereby leading to further complications perhaps with a fatal issue.

THE OPERATION

Rather than describe the technique of this method of treatment in general terms it may be better understood by describing it in a typical case as for example one in which the upper end of the tibia is the seat of acute osteitis when the operation would be conducted as follows—

General anaesthesia—Provided that this is well administered there need be no special preference given to one type over another.

Preparation—A tourniquet applied to the thigh should be considered essential for without it the patient may lose a considerable amount of blood and children, who form the majority, do not withstand hemorrhage well. The skin of the whole leg distal to the tourniquet should be cleansed with 1 in 20 carbolic or other antiseptic. A sandbag is placed so that the leg will rest upon it and the sterile towels arranged in position.

Incision—A free vertical incision is made down to the bone with its centre over the focus indicated previously by the most tender spot that is found on the antero-internal surface of the tibia. The periosteum will usually be seen to be oedematous indicating underlying mischief while in some cases an actual subperiosteal abscess will be encountered when the pus is evacuated and the abscess wall cleaned gently by mopping it. The incision in the periosteum should be long enough to give a satisfactory exposure of the underlying bony surface.

Removal of the bony focus—The focus is sought for in the suspected area by drilling which is stopped as soon as pus is seen to emerge from a drill hole. The bone is now opened up with a gouge and every visible trace of inflamed cancellous tissue removed the opening being enlarged only as far but no further than is necessary for this purpose. The medullary cavity must not be opened unless the infection has spread into it and such an opening is regarded as necessary for the efficient removal of purulent contents. It may be difficult to know when one has come to the margin of the diseased area but ordinarily this is not so for the yellowish white purulent focus contrasts greatly with the normal reddish cancellous tissue. The absence of pus on drilling—a rare occurrence—should not affect the decision to open up the bone for a purulent focus may be discovered only when this is done. In early cases no pus may be found at all but there will be a focus consisting of tissue that is softer in consistency and more hyperaemic than normal cancellous tissue. Occasionally pus may exude from a drill hole and yet on opening up the bone no more may be found what little there was having escaped through the hole; in such a case however a definite focus of soft and hyperaemic tissue will be found. From the foregoing description it will be seen that a gutter operation has been performed with the specific purpose of removing the focus of infection in the bone but it is emphasised that the amount of guttering done must only be commensurate with efficient removal of the infected tissue and that unnecessary opening up of healthy tissue is to be strongly deprecated. This type of operation has the added advantage that in the event of some of the infected tissue being left behind the opening in the bone is large enough to provide adequate drainage.

Disinfection of the wound—The whole of the wound cavity is thoroughly mopped out with methylated spirit and then dried. The spirit is not only an efficient cleansing agent but, by its dehydrating action, leaves behind a dry surface to which the Bipp can adhere. Some Bipp is put on a dry gauze and rubbed into every part of the bone cavity and wound surface and all excess is removed, there being left behind only a thin covering of the paste over the exposed tissues.

Closure of the wound—The bone cavity is now packed with a Bipped gauze and the wound closed with interrupted sutures of thick Bipped silk except for the gauze exit, which leaves a passage for discharge. The packing of the cavity is advantageous since the gauze acts as a preventive against the hæmorrhage which would otherwise take place on removal of the tourniquet, and if some infected tissue has been left behind the organisms would find an ideal pabulum in the blood which would fill the cavity in the absence of the gauze. It is found that sutures of thick silk tend to cut through the skin much less than those of silkworm.

Dressing—Sterile boric powder is sprinkled liberally over and around the wound and a dressing put on consisting of dry gauze and abundant wool. The limb is then immobilised by fixing it on a back splint with Gooch side splints or plaster of Paris may be used for this purpose if preferred. The tourniquet is removed and the limb elevated.

AFTER TREATMENT

Should hæmorrhage appear on the bandage—a rare occurrence—methylated spirit is poured over the stains and after this has been done the hæmorrhage will usually cease. Unless the patient should feel that the dressing is uncomfortable or there is much discharge—also rare—it is not touched for 10–14 days, when a general anæsthetic is given, the dressings and the sutures removed, the wound opened, and the gauze taken out. It will be seen that all the wound cavity is clean and lined by healthy granulation tissue.

The treatment of the cavity now comes under consideration. Should it be small no further treatment is necessary, and the wound, after being cleaned afresh with methylated spirit and a thin layer of Bipp applied to its surface, is closed again with interrupted sutures of thick Bipped silk. Following this there is usually little or no discharge and at the end of another 10–14 days the wound may be found to have healed entirely. Should there be any discharging area at this time, two or three weeks will usually suffice for its cessation.

When dealing with larger cavities it is advisable to resort to some means of attempting obliteration and the best method of doing this lies undoubtedly in the use of the pedicled muscle graft. In the situation under review—namely, the upper end of the tibia—such a graft is easily obtainable, it being possible to use either the tibialis anticus or the soleus, although the former is preferable as the operation is likely to be more easily accomplished. The cavity will have to be enlarged by removing the adjacent part of the crest of the tibia as the base of the graft must not lie over a ridge of bone, since the blood supply to the distal portion of the graft would probably be seriously jeopardised. The graft is cut with its base proximal to ensure the blood supply necessary for its survival, Bipped and laid in the cavity. The wound is then closed, as before, without drainage. While such a wound may heal by first intention, there may be a small amount of discharge which only calls for infrequent dressing and will probably cease in a week or two. The result of this method of dealing with the cavity is that a scar is formed consisting of the full thickness of the skin.

Mention of the use of free fat grafts should not be omitted when considering the obliteration of a bone cavity, for it is often successful. The grafts are usually easily obtainable from the thigh, gluteal region, or the abdominal wall, and this method is particularly valuable in situations where it is impossible to obtain a pedicled muscle graft such as the lower end of the tibia. On the whole, however, the muscle graft is to be preferred.

FIGS 1 and 2.—Temperature charts in two fatal cases.

Unless the gutter made in one of the long bones of the inferior extremity is exceptionally large, it is safe to allow weight-bearing some two months after the institution of treatment.

COMMENTS

There are several observations on this method of treatment which might well be made here. On the day following operation the temperature usually begins to descend and in some cases drops to normal in a dramatic manner, to remain afebrile. The absence of post operative pain is remarkable and gratifying, for the intense pain experienced before operation will be found to have disappeared when the effects of the anæsthetic have worn off. In my earlier cases even large cavities were packed and allowed to heal by granulation, but this method of procedure has the disadvantage of taking three or four months before healing is complete, and it results, when a subcutaneous bone such as the tibia is involved, in a thin scar adherent to bone, although it is only fair to state that it is by no means necessary to wait until such a cavity has healed completely before getting the patient up and allowing him to walk or attend school, for a weekly dressing is all the care that is required. However, it is obvious that this is a poor method of dealing with a bone cavity when compared with the quick and efficient closure of such a cavity as described above.

It will have been noticed that, in the description of the Bipp method of treatment, no mention was made of the formation of sequestra, the apparently common result and bugbear of other forms of treatment of acute osteitis. The truth is that apart from the flaky variety that are discharged naturally without any trouble to the patient, sequestra do not form and that secondary operations for their removal are therefore not necessary. It is interesting to consider the reasons for this remarkable absence of sequestrum formation. At operation it is usually impossible to tell what amount if any, of the dense bone is either already dead or likely to die, but there seems no doubt that by the guttering over the focus of infection much of the dense bone which has necrosed, and which would later separate as a

sequestrum is removed. Also the provision of such adequate drainage combats the risk of further necrosis due to tension which might occur as a result of the inability of the products of inflammation to escape sufficiently quickly if by any chance they were not completely removed at operation. Further more from what has been said about the bacteriological action of Bipp the absorption of the iodine seems to control the infection even when it has spread into the tissues around the excised area this control leading to diminution of inflammation and therefore of tension and so helping to avoid the formation of sequestra. These reasons appear to explain satisfactorily the absence of sequestration following the treatment of acute osteitis by the Bipp method.

Lastly it will have been realised that the technique of this method is relatively simple this in itself being a commendation for its employment.

Résumé of Personal Cases

The series reported here numbered 21 patients, all of whom were operated upon during the past six years at the Royal Victoria Infirmary Newcastle on Tyne and the Thomas Knight Memorial Hospital Blyth. This number though not large in itself has provided sufficient personal experience to substantiate certain claims that will be made for this method of treatment.

In 15 cases there was a definite history of injury and of 10 in which a bacteriological examination of

infected tissue was made a growth of *Staphylococcus aureus* was obtained in 18 no organism being grown from the remaining one. The ages varied between 3 and 17 11 of the patients being under 12 and the remaining 10 over that age. As regards sex and the bones affected this series agrees very much with others which have been reported. There were 14 males and 7 females a proportion of two to one in favour of the former. Table II shows the bones affected. From this table it will be seen that the femur was the bone accounting for a third of the cases and that the femur and tibia combined comprise just over a half of the total number. It is also of interest to recall that the lower ends of the femur

fibula and radius and the upper ends of the tibia and humerus are the more actively growing ends of these bones.

In general terms the aims of treatment of acute osteitis may be said to be first the preservation of life, and second the preservation of growth and function and the results given below indicate the degree to which they have been achieved by the Bipp method of treatment in the present series of cases.

FIG 4.—Late result in a case of acute osteitis of the right femur treated with Bipp. There was no deformity or shortening. Knee-joint shown in full flexion.

of fatal cases (1) fatality with discussion (2) complications which arose before discharge from hospital (3) length of stay in hospital.

Fatality with discussion of fatal cases.—There were 2 deaths in this series a fatality rate of 9.5 per cent a rate much lower than most of those shown in Table I. While it is realised that it is manifestly unfair to judge any method of treatment on fatality alone because of those patients who are so ill when first seen by the surgeon that their fate is not decided by operative treatment yet human nature such that a method which has been shown to be associated with a low mortality will always be regarded with more enthusiasm than one that has resulted in a larger percentage of deaths.

The first fatal case was that of a boy, aged 16, who was admitted to hospital with great pain in the much swollen region of the left shoulder. The patient had been delirious while at home and on admission he was obviously very ill, having a temperature of over 101 F, a rapid and weak pulse, sore on the lips and sunk in eyes. At operation a large subperiosteal abscess was found and nearly all the cancellous tissue of the upper end of the humerus was purged but the infection had not involved the medullary cavity of the bone. Between the time of his operation and his death four days afterwards he developed a left-sided parotitis and an effusion into the left knee joint. His temperature shown in Fig 1 came down to normal on the day following his operation but then rose again to over 104 F just before he died. A post mortem examination was not obtained.

Most surgeons with experience of acute osteitis have met cases which when first seen by them were obviously suffering from an overwhelming blood stream infection of the nature of a septicæmia or septicæmia. About such cases there appears to be general agreement that the condition is due to the virulence of the organism to the lack of resistance of the patient or to a combination of them and that no treatment either conservative or radical is likely to be of any avail the patient doom to die, already sealed. I believe this to have been such

FIG 3.—Temperature chart of a typical case of acute osteitis treated with Bipp indicating length of stay in hospital.

infected tissue was made a growth of *Staphylococcus aureus* was obtained in 18 no organism being grown from the remaining one. The ages varied between 3 and 17 11 of the patients being under 12 and the remaining 10 over that age. As regards sex and the bones affected this series agrees very much with others which have been reported. There were 14 males and 7 females a proportion of two to one in favour of the former. Table II shows the bones affected. From this table it will be seen that the femur was the bone accounting for a third of the cases and that the femur and tibia combined comprise just over a half of the total number. It is also of interest to recall that the lower ends of the femur

a case. It is reasonable to assume, however, that some of these cases, if not a fair proportion of them, have passed through a stage of the disease when surgical treatment would have saved their lives. The boy mentioned above had been ill at home for almost two weeks before admission to hospital, and it is probable that recovery would have followed more

FIG 5—Late result in a case of acute osteitis of upper end of left tibia treated with Bipp. Absence of deformity or shortening. Full extension of knee joint. Note the broad adherent scar, the result of healing of the bone cavity by granulation, and compare with Fig. 10.

pain of sudden onset in the region of the end of one of the long bones, who has a point of exquisite tenderness in the same region, and who has an elevated temperature must be regarded as a potential case of acute osteitis and surgical opinion sought without delay.

The second case was that of a girl, aged 3, with acute osteitis of the lower end of the fibula. At operation only a small purulent focus was found and removed. After operation she appeared to be well for five days when her temperature rose to over 102° F (Fig. 2) and signs of a broncho pneumonia developed, but with no pain suggestive of pyæmic infarction of the lung. Her temperature fell again but then remained elevated for several days before she died nearly three weeks after operation. During this time the wound itself appeared to progress favourably, there being no clinical evidence suggestive of local spread of infection.

It certainly could not be said that this patient came under the category of having an overwhelming infection at the time of her admission to hospital, for there was then no apparent reason why recovery should not take place and consequently the final outcome was an unexpected disappointment. Unfortunately an autopsy was not allowed.

Complications occurred in 6 of the 19 surviving cases but in 4 of these they were of little consequence, consisting as they did of superficial pyæmic abscesses that healed in less than two weeks after being opened and drained. In 3 of the 4 cases only one abscess formed while in the remaining 1 there were two.

Of the 2 cases in which more severe complications occurred, the first was one of acute osteitis of the lower end of the femur. At operation there was found a large subperiosteal abscess and involvement of the bone to such an extent that a gutter about 6 in

long was required to reach the upper limit of the purulent focus. Unfortunately an accidental fracture occurred. Turbid fluid aspirated from the adjacent swollen knee joint at the time of operation yielded, like the pus from the bone, a growth of *S. aureus*. Since the patient complained of no further pain after operation and the swelling of the knee joint gradually subsided, no further treatment of this mild septic arthritis appeared to be indicated and none was undertaken. Further reference to this case will be made when considering restoration of function and sequestrum formation.

In the second case the tibia was the bone involved, there being a large subperiosteal abscess and spread of the infection into the medullary cavity. The operative treatment proved a failure as both the knee and ankle joint became involved and eventually the leg was amputated through the thigh as a life saving measure. After this the patient quickly recovered. There seems no doubt that the failure of the treatment was due to the leaving behind of infected tissue at the first operation.

Each of these patients had been ill for nearly two weeks before coming to operation and illustrate well how delay in diagnosis may militate against success of treatment by permitting of the spread of infection, thus not only undermining the general condition of the patient but also increasing the risk of operative accidents or errors in technique which ordinarily are readily avoided.

Length of stay in hospital.—Very little is mentioned in the literature of the length of time patients suffering from acute osteitis are kept in hospital. Ogilvie (1928), reporting a series of 51 cases from Guy's Hospital, found that the average length of stay in hospital was 2 months 12 days—i.e., approximately 72 days—omitting fatal cases and two others who were in for a longer period. These figures indicate how the disease may be of such a protracted nature as to impose severely upon the bed accommodation of any hospital, and sight should not be lost of the important fact that the longer the duration of the illness the worse is the functional result likely to be. It is therefore of interest to contrast these figures of Ogilvie's with those in the present series. Of the 19 surviving cases, 14 were in hospital under 28 days and 2 others under 35 days. The remaining 3 were in hospital for longer periods, 2 of them being the complicated cases mentioned above and the third one of acute osteitis of the lower end of the femur where the wound was packed and allowed to heal by granulation, the home conditions of this patient being such that it was considered advisable to keep him in hospital until the wound had healed completely. The length of stay in hospital of these cases was 59, 95, and 75 days respectively. Fig. 3 is a temperature chart of a typical case of acute osteitis treated by the Bipp method and indicates the short duration of their stay in hospital.

LATE RESULTS

These may be considered conveniently under the following three sections: (1) growth and function, (2) sequestrum formation, (3) recurrence of infection.

Growth and function.—There is an unfortunate lack of information on the late results of acute osteitis concerning growth and function in spite of the fact that, in endeavouring to assess the value of any particular method of treatment, this aspect of the disease must always form an important consideration. Most articles on the subject, while giving prominence to the method of treatment

employed by the author and the mortality associated with it, often omit altogether to mention the effects of the disease on those who were fortunate enough to recover. In no case of this series has the growth of the involved bone been other than normal there being neither shortening such as might be caused by extensive damage to the epiphyseal cartilage nor any irregularity of growth with resulting deformity such as might occur with its partial destruction. The function of the adjacent joint has only suffered in one case where an acute osteitis of the lower end of the femur was complicated by a septic arthritis of the adjacent knee joint there being now only about 10° of movement present.

Figs 4 and 5 are photographs of two typical cases taken to show the absence of shortening or deformity and the preservation of function of the adjacent joint.

Sequestrum formation.—In published reports the formation of sequestra following acute osteitis appears to be the rule rather than the exception although here again the information given is often vague. In the present series the remarkable absence of this feature which is the chief cause of persistent discharge and which often renders further operation necessary is therefore noteworthy. In 3 cases tiny flaky sequestra formed and were discharged naturally without any trouble to the patients. In only one case did a sequestrum form which was large enough to need a second operation for its removal; the femur was accidentally fractured and this was apparently responsible for interference with the blood-supply to a portion of the bone and for the consequent necrosis. In view of the absence of sequestration in other cases in this series where large gutters were made, there is reason to believe that had the fracture not occurred in this case also there would have been no sequestrum formation. Mention has already been made of the suggested reasons for this absence of sequestrum formation after using Bipp.

Recurrence of infection.—From some months to six years have passed since the cases in this series were operated upon and while this short post-operative history is long enough to provide accurate information about the effects of the disease on growth function and sequestrum formation it is not long enough to establish with anything like the same certainty the degree of liability to recurring infection which is one of the well recognised characteristics of acute osteitis. It may be either in the same or another bone though usually in a less acute form it being not uncommon for this to take place as long as 30 years or more after the initial attack. Consequently the absence of recurrence in this series of cases except in one instance is recorded to complete the investigation of the late results and not as an attempted proof that recurrence is less likely to take place following the Bipp method of treatment than after any other for many years must still elapse before accurate information can be obtained on this point.

The case in which recurrence took place was one where the bone originally involved was the left tibia. Three years later the boy was brought complaining of a gradually increasing swelling above the right knee with a dull boring pain in the same region. The pain and swelling had been noticed first about three months before the boy was brought for examination the condition thus being chronic in contrast to his former acute illness. During the three months the boy had remained in good general health. At operation a purulent focus about 1 cm. in diameter was found in the lower end of the femur requiring a limited operative procedure for its removal. The Bipp

method of treatment was again carried out and the patient had an uninterrupted convalescence. Bacteriological examination showed the presence in the focus of the *S. aureus* the same organism as that found on the first occasion.

(To be concluded)

DIAGNOSIS AND TREATMENT OF GASTRIC AND DUODENAL ULCER

By DUNCAN LEYS D.M. Oxon. M.R.C.P. Lond.

PHYSICIAN TO THE SELLY OAK HOSPITAL, BIRMINGHAM

RADIOLOGY has revolutionised diagnosis prognosis treatment even the classification of disease processes in many parts of the body and it is no longer permissible to leave any patient in whom symptoms of indigestion have persisted or recurred for some weeks or months without X-ray examination. None of the older methods available for the diagnosis of ulcers whether benign or malignant are entirely reliable. A few will certainly escape X-ray diagnosis also but if a chronic ulcer is present skilful radiology will disclose it on the first or second examination. An ulcer may give rise to no pain vomiting or alteration of appetite no tenderness may be found when the patient receives the ordinary clinical examination. The test meal may show a normal or low percentage of acid or free acid may be entirely absent. The benzidine test may show no trace of blood in either test meal or stool.

The apparent incidence of ulcer amongst a group of patients with persistent or intermittent dyspepsia may increase by 100 per cent. or more when the X-ray diagnosis is made by an experienced interested, and careful radiologist until it becomes a matter for surprise when clinical expectations are denied by the Röntgen rays. The degree of discomfort to the patient and his readiness to submit to repeated investigation bear also a simple relation to the skill of the radiologist.

The fluoroscopic examination is obviously of the first importance but it is a preliminary to the permanent record of the site of the ulcer and it is unnecessary for physicians who have neither time nor training enough to make their own X-ray diagnosis to be content with merely a verbal report. I made a clinical diagnosis of ulcer in 58 patients attending my clinic at Selly Oak Hospital in 1936. Dr B. T. Hooper radiologist to the hospital was unable to make a permanent record in only 3 of these cases. The reliability of skilled radiography does not of course excuse the omission of any of the older methods of diagnosis; the physician has in any case to make the preliminary diagnosis and must have in mind all the possibilities if serious cases are not to be missed nor the time of biochemist and radiologist wasted.

DIFFERENTIAL DIAGNOSIS OF CARCINOMA

Although it is possible to lay down a number of clinical criteria by which carcinoma of the stomach may be differentiated from simple ulcer it may be said that in individuals of appropriate age nothing except satisfactory Röntgen ray examination is sufficient to exclude it; there are rare cases in which only histology can do so. Nevertheless given adequate radiological help there should be no difficulty in promptly distinguishing the majority of cases of carcinoma of the stomach as soon as the patient seeks advice and mercifully it is a relatively uncommon

disease (It is, however, not encouraging to realise that in nearly six years of busy hospital practice, I have not seen a single patient with carcinoma of the stomach whose life has been usefully prolonged by surgery)

SILENT BLEEDING

Gastric ulcer is an important cause of hypochromic anæmia. It is true that most patients with ulcer have pain, and that the presence of an ulcer is therefore not likely to be overlooked, it is also true that if gastric analysis shows a complete achlorhydria in patients whose only symptoms are those of anæmia, iron deficiency is the likely cause. But it is safest to assume, until proof to the contrary is forthcoming, that (1) a patient with achlorhydria and long standing indigestion, whatever the age, and (2) a symptomless patient who has anæmia with free hydrochloric acid in the stomach, both have gastric or duodenal ulceration. It is in any case a serious mistake to treat any patient for anæmia without both blood count and gastric analysis, and even the absence of a positive benzidine reaction in the stools does not warrant the assumption, in either of the two eventualities cited, that no ulcer is present. I have seen cases misdiagnosed for months as Banti's disease or Wits's anæmia, and even the label of petit mal attached to a man who had had several attacks of fainting from periodic loss of blood from an ulcer which had not caused other symptoms severe enough for him to complain of them. Experience also, and not imagination, prompts the warning that "hæmorrhagic diathesis" and "gastrostaxis" are *probably* the result of a bleeding point in the base of a chronic ulcer. Diffuse oozing of blood from the gastric mucous membrane has been seen both at operation and post-mortem, thrombosis of the splenic vein can cause it. But a clinical assumption that gastric hæmorrhage has originated in this way is scarcely justifiable.

In general, local tenderness, as ordinarily tested, is an extremely unreliable sign of ulcer. The radiologist may elicit tenderness when the clinician does not, since the ward examination is made in bed, without knowledge as to the site of the ulcer, whereas the radiologist has his patient standing, with the stomach more accessible, and can direct his finger to the exact point where he sees the barium clinging to the ulcer base. Under such conditions the presence or absence of tenderness can be, especially on repeated examination, a good indication of the state of healing.

GASTRIC ANALYSIS

The fractional test-meal rarely if ever makes a diagnosis, but it can provide useful confirmatory evidence. In gastric ulcer the highest value for free acid in the fractional test-meal scarcely ever exceeds 0.2 per cent, and it may be completely absent from all specimens (2 cases in a series of 39 proved cases of gastric ulcer). It is frequently over 0.3 per cent when duodenal ulcer is present, and I have never seen complete achlorhydria with duodenal ulcer, although several specimens, and not necessarily the early ones, may show no acid.

The presence of blood is very significant, and it is never safe to assume, unless repeated examination later shows a complete absence of blood, that hæmorrhage, even in minute amount, is traumatic. Similarly, a positive benzidine reaction in the stools should always be taken as evidence of bleeding. In my experience it is unnecessary to get the subject of the test to abstain from meat, fish, or vegetables in order to avoid "false positives". I have on several occasions tested the point by asking a normal person

to take a milk diet, successively adding greens, fish, and meat to the diet, and have never found the test become positive.

HEALING

The rapidity with which the X ray shadow of an ulcer crater may disappear, under favourable conditions, is astonishing. Ulcers known to have been present at the same site for ten years will disappear in half that number of weeks. It has been questioned (see, for example, Rehfuess, 1927) whether the disappearance of X ray crater shadows can be accepted as conclusive evidence of healing, but even if one discounts the initial rapid diminution in size as due merely to the disappearance of local muscle spasm, there can still be followed the narrowing of the residual pit to a V shaped depression, and its ultimate disappearance, coincident with the disappearance of blood from the stools and tenderness on deep palpation. There seems no reason to doubt that the ulcer has healed, whether or no it remains so is not so obvious.

The accompanying tracings of ulcer craters taken from the radiograms of some of these cases are records of the actual time taken for chronic ulcers to disappear, they are drawn from films taken by the same radiologist, with the same technique, and give largest dimensions of the ulcer as it appeared in the films.

Neither age nor sex appeared, in this small series, to be factors of importance for healing except in so far as older patients tended to have larger and more chronic ulcers (there were, however, two patients whose first symptoms appeared after the age of 70). Of very great interest are those cases, fortunately rare, in which, while treatment is still being applied, an initial rapid healing is followed by some retrogression, as in Cases 9 and 23 figured below. In the latter case, recurrence of symptoms coincided with retrogressive changes in the radiogram and both with an attack of acute rheumatism. While more spectacular pictures of healing are obtained with gastric than with duodenal ulcers, on account of their greater size, and while the general tendency is certainly for more rapid progress to be made in the gastric cases, some remarkably quick cures have been seen in patients with duodenal ulcer. Rehfuess regards residual duodenal deformity as evidence of incomplete healing, but post-mortem and surgical experience show that the scar of a chronic healed ulcer can produce it, and clinical evidence seems to point to the same conclusion.

Absence of pain, of discomfort, of nausea and vomiting, of local tenderness, of blood from the stools—none of these things can be taken as evidence of complete healing. Six cases in this group had no blood in the stools when repeatedly examined, during the whole period of observation in hospital, and it is a common experience to find X ray evidence of an ulcer still present after the benzidine reaction has changed from positive to negative. From the observations of Faber (1935) it is certain that the gastric wall is permanently diseased in many cases before ulcer develops, and it is the obvious duty of clinicians to discover what are the factors which predispose to the breaking down of the mucous membrane and what to its healing. One set of factors may quite possibly be the reverse of the other.

THE SITE OF THE ULCER

Although the opinions expressed in this paper have been formed over a period of many years, the cases actually under review number only 58, and represent rather less than a single year's experience from

the wards under my care at Bely Oak a year during which X ray co-operation has been exceptionally good. Gastric ulcers were almost twice as common as duodenal, a finding which is contrary to the usually accepted incidence, stated by various authors to be $D U : G U = 3 \text{ or } 4 : 1$ (Osler and Macrae 4 : 1; Relhass 3 : 1 or 4 : 1; Shelton Horsley at least 4 : 1; Crohn several "duodenal ulcers to every gastric ulcer"). I wish to call attention to this discrepancy since although the number of cases reviewed is not large it is as large as the number of cases upon which most of these estimates were based, and the probability of finding fortuitously in my unselected

barely recognised. It is possible that some patients who attended my clinic or were admitted to my wards during the period under review were suffering from ulcer but have not appeared in this review owing to lack of evidence on which to base a diagnosis but the risk of their numbers being large enough to upset conclusions based on the belief that all cases of ulcer seen are included is small. By the nature of the symptoms it is improbable that chronic ulcers were missed and acute ulcers being all the more likely to be the site of haemorrhage would be brought to notice when the stools were examined.

This is not a mere academic point. Several facts suggest that the site of the ulcer may have some bearing on aetiology: duodenal ulcer occurs at an earlier age is more common among men than women and seems to be immune from carcinomatous change; duodenal ulcer occurs with equal frequency among poor and rich but gastric ulcer is twice as common among the poor.

TREATMENT

Certain facts must be kept in mind in attempting to assay any special line of treatment or in drawing conclusions as to aetiology from its apparent success:

(1) Healing undoubtedly takes place quite often in a gastric ulcer without the patient having been either put to bed or ordered any special treatment beyond advice as to diet. (This latter may of course be an all important point but it is not the obvious factor since healed cases may have been given very different diets; there is however one factor in common in almost all systems of gastric ulcer dieting—4 e milk.)

(2) Healing usually takes place more quickly in hospital than at home even if good conditions including rest in bed are employed at home.

(3) Pain from gastric ulcer disappears almost immediately if the patient goes to bed no matter what diet is taken (excluding however gross indiscretions).

(4) Cases frequently occur in which healing does not take place or in which healing occurs but is followed by recurrence of ulceration notwithstanding prolonged rest in bed and milk diet.

(5) Alkalies and bismuth while appearing to relieve the pain of duodenal ulcer are powerless per se to effect a cure and have no effect either on the symptoms or the size of the lesion in gastric ulcer.

If these facts are remembered there is at present no evidence that any special line of treatment such as injections of histidine has any influence upon the course of the disease nor has there yet appeared any account of the conditions under which ulcer develops which can pretend to implicate any special set of circumstances.

Gastric ulcer is known to be common among all classes and a study of the type of work performed by the men in the present series yields no information of apparent significance: the work ranged from the purely sedentary to navvying. It is possible that heavy stress and anxiety all play a part but no close association has as yet been described as existing between e.g. ulcer and anxiety states.

The nature of the diet seems on the face of it a very promising line of inquiry. It is already known that mere trauma can continue for a life time without causing ulceration: what other factor can be involved? McCarrison is quoted by Relhass (1937) as having suggested the possibility of vitamin deficiency and there are many things to make diet deficiency plausible as a working hypothesis. Thus a long period of unemployment has preceded symptoms in several of my cases the onset of symptoms coinciding with a return to work. It might account for the class difference in mortality from gastric

Tracings from X ray films of healing gastric ulcers

series twice as many gastric as duodenal ulcers if the true incidence in the general population is $D U : G U = 4 : 1$ is one in many hundred thousands. The probability is still exceedingly small if the incidence is taken as $D U : G U = 1 : 1$.

For myself I think the explanation is that while careful radiography gives the site incidence in an unselected group of cases standard text book estimates are founded on surgical experience and perforation the common indication for interference is much more common in duodenal than in gastric ulcer ($D U : G U = 0 : 1$ according to Maingot's 1st graduate Surgery). The incidence found in my series of cases can hardly be due to the earlier recognition of gastric than duodenal ulcer by radiography since out of 48 clinically suggestive cases only 3 were left undetermined by X rays. Before surgical intervention was common gastric ulcer was reckoned to be frequent and the occurrence of duodenal ulcer

ulcer shown in the Registrar-General's Decennial Supplement. The one factor common to every type of treatment employed is a diet which includes a high proportion of milk, butter, and fish. Gastric ulcer is notoriously a disease of remissions and relapses such as are characteristic of several deficiency diseases.

It has at all events seemed to me wise to give all patients with ulcer of stomach or duodenum large doses of vitamin A because of the evidence of its great importance in the life and growth of epithelial tissues, and because we are ignorant as to the optimum intake. Patients have been rested and have taken a simple diet with a high proportion of first class protein, but no other treatment has been given beyond paraffin as required for constipation and if requested by the patient, and iron when there is anæmia. It is under these conditions that very rapid healing of ulcers has taken place. That unwise therapeutic limitation of diet may be a cause of delay in healing is very likely—it is already known to have given rise to iron deficiency anæmia, and one patient in this series, who, when he was admitted to hospital, was known to have had an ulcer for ten years, was proud of the fact that he had, according to his doctor's reputed instructions, lived during the whole of that time without fresh fruit, vegetables, or meat. I have seen another case in which a severe polyn neuritis leading to permanent disability developed after a very prolonged abstinence from meat and fish.

Specific factors apart, all patients with ulcer who have anything less than the full 100 per cent of hæmoglobin require a supply of iron in addition to their diet. Neglect of this factor in treatment may delay cure of anæmia for many weeks, although all hæmorrhage may have ceased. *Provided adequate precautions are observed*, there can be no question that the risks to a partially exsanguinated patient, even on those rare occasions on which it is possible to be certain that all bleeding has stopped, of death from infection in an open hospital ward, or from exhaustion or further loss of blood, are much greater than the possible ill effects of blood transfusion. Personal experience has made me very sceptical of the theory that transfusions of 20 ounces of blood are prone to provoke further hæmorrhage, or to harm the patient in any way. Pygott (1937) points out that in reported cases of death following blood transfusion when blood incompatibility has been excluded, there is reason to believe that the heart or vessels have always been diseased, and that no death has been reported as following the immense numbers of transfusions carried out for hæmorrhage.

SURGERY

My experience of surgical remedies for gastric and duodenal ulcer has been uniformly unfavourable. Particularly does one dread the patient with an ulcer, whether gastric or duodenal, for which any form of short circuit operation has been performed. Even symptomatic improvement is very difficult to obtain in such cases once symptoms have recurred, and one is strongly inclined to attribute initial improvement and subsequent freedom from symptoms, following gastro-enterostomy, to factors other than the surgical operation. Although greater caution is now exercised by surgeons in their selection of cases, and the fashion for wholesale short circuit and excision operations is mercifully on the wane, it is still common enough for a surgeon to consider himself entitled or even obliged to interfere when the diagnosis of chronic ulcer is made. Shelton Horsley, for example, states, "an operation on a gastric ulcer should not long be delayed."

In view of the obvious ease with which cure can almost always be obtained by perfectly safe means, operation for excision of ulcers is, in my opinion, entirely unjustifiable. Initial mortality is great, and the evidence for subsequent freedom from symptoms unsatisfactory, unless, as is sometimes the case, *real attention is paid for years to "medical" treatment* after operation. The removal of such a bulk of tissue, often including that part of the stomach concerned in the manufacture of the hæmaturic principle, is an added danger to the patient.

One is not even entirely convinced that the appreciable mortality, even in expert hands and with local "splanchnic anæsthesia," warrants operations for hour glass deformities and pyloric stenosis unless they are so gross as to exclude the possibility of safe remedies making a tolerable life possible. My impression is that every case in which X rays disclose such deformity should be given several months of "medical" treatment—i.e., rest, physiological diet, and possibly stomach lavage—before operation is considered. The whole of the deformity seen at the first examination is not necessarily permanent.

If one excludes (as recent controversy and personal experience surely entitles one to do) gastrectomy for hæmatemesis as being anything more than a last resort after repeated transfusions have failed to keep pace with bleeding, perforation remains the sole ordinary indication for surgical interference in gastric or duodenal ulceration, and, with the knowledge available, this complication should already be less frequent than it is.

SUMMARY

1 X ray examination of 58 consecutive cases, clinically diagnosed as peptic ulcer, demonstrated the ulcer crater in 55.

2 Gastric ulcer in this series was twice as common as duodenal (a reversal of the commonly accepted proportional incidence). Reasons are given for thinking that the older estimates of incidence were based on a surgical selection of cases.

3 Ulcers known to have been present for at least ten years have been shown to heal in a few weeks under certain conditions, the significance of which, as regards ætiology and treatment, is discussed.

ST BARTHOLOMEW'S HOSPITAL, LONDON.—The governors of this hospital have under consideration a scheme for the erection on a site adjoining the hospital of a special ward block financially independent of the hospital but which would be able to call upon the special services of a large general hospital. This block would be open to persons with incomes of between £250 and £500 whom the hospital by its charter is at present debarred from helping. It is anticipated that the new block would be ultimately self supporting but a capital sum of about £120,000 would have to be found for the building and equipment. No appeal is at present being made to the public but those interested may obtain further information from Sir Gordon Campbell at the hospital.

TUBERCULOSIS IN WILD VOLES

By A Q WELLS D.M. Oxon.*

PATHOLOGIST TO THE BUREAU OF ANIMAL POPULATION IN THE UNIVERSITY OF OXFORD

(From the Sir William Dunn School of Pathology)

Griffith (1930) states that tuberculosis in warm blooded animals living wholly in the wild state is unknown. The object of this paper is briefly to report a widespread occurrence of tuberculosis in voles—*Microtus agrestis*. These animals are subject to a cycle of population increasing over a period of three to four years and then decreasing suddenly to a low figure in one or two months (Elton et al 1935 Findlay and Middleton 1934 Elton et al 1935 (in preparation)).

The possibility of this sudden decrease being due to epidemic disease has been the subject of my investigation of which this is a preliminary report.

For the past twelve months the field service of the Bureau of Animal Population in the University of Oxford has enabled me to examine voles both dead and alive from areas in Scotland Wales and England which are uncultivated and fenced off from domestic animals. The Bureau after much experiment has established a system of live trapping and transport of the voles to the laboratory where they have been kept in isolated cages.

On Jan. 20th 1937 a vole died which had been in the laboratory for a little over one month. The post mortem examination showed caseous areas throughout the subcutaneous tissues of the body involving the glands of the neck axilla inguinal region and back with ulceration of the skin round the right plume. Both lungs contained caseous areas with sharply defined edges, the mediastinal and mesenteric glands were much enlarged and caseous, the spleen was enlarged. The caseous material in the subcutaneous tissues contained a very large number of acid fast bacilli which have the morphology of *Mycobacterium tuberculosis*. The caseous areas in the lungs similarly contained a great number of acid fast bacilli but there was in section very little cellular reaction. Cultures made from the caseous material yielded no growth on nutrient agar but growth was visible after six weeks on Dorset's egg and I troff's medium. The nature of the growth and the morphology of the organism were similar to that of *Mycobacterium tuberculosis*.

An emulsion of caseous material from several voles similarly infected has been injected either subcutaneously or intraperitoneally into laboratory bred voles guinea pigs and rabbits. The disease has been reproduced in the voles with death of the animals; three guinea pigs have died with widespread disease of the organs, in which acid fast bacilli are present. Large local lesions have occurred in the rabbits without so far causing death. All the guinea pigs and rabbits have become reactors to tuberculin in about one month after inoculation.

Since February 1937 131 voles have been found with macroscopic tuberculous lesions in which acid fast bacilli have been demonstrated. These have been sent from seven different stations in the British Isles. Ninety two of these infected voles have arrived dead or have been killed on arrival. There is therefore no doubt that the infection has occurred in the field and not in the laboratory.

Although some facts about the bacterium in question are not yet known it seems highly probable that it is *Mycobacterium tuberculosis*. If it proves to be so several points of interest arise. The existence of

tuberculosis in wild animals may have some importance in the spread of the disease to man and domestic animals; the use in the laboratory of an animal which naturally contracts the disease may be preferable to the use of the animals used hitherto which are not known to have the disease in nature and the fact that a small animal easily maintained and bred in captivity here, is available for epidemiological study may throw some fresh light on tuberculo-

The organism is being typed by Dr A Stanley Griffith of the Field Laboratories University of Cambridge. I am indebted to him for his advice.

SUMMARY

The presence of disease presumed to be tuberculosis in wild voles is reported. The fact that the disease is widespread in the British Isles suggests that this is not a chance infection.

AUTOSEROTHERAPY FOR DRUG ADDICTION

By MARGARET VIVIAN L.S.A.

Drug addicts have long been the *blues notes* of the medical profession and it is common knowledge that a long-standing case is an almost hopeless proposition when treated by the ordinary methods of gradual withdrawal or sudden deprivation. In the past I have tried to help many of these unhappy people. Many of them insisted on leaving the nursing home while still needing small doses of morphine and of those that endured to the end the majority sooner or later relapsed because they found themselves unable to cope with their daily work without their accustomed stimulant. These patients are usually the victims of circumstance and I am glad to be able now to record greater success in their treatment.

The method used (auto serotherapy) consists in the hypodermic injection of fluid obtained from blisters raised by applying irritant plaster to the patient's skin the amount injected being usually 5-10 ccm at a time. In the treatment of drug addiction this method was first described I believe by Modinos of Alexandria in 1929 but I did not see his paper until some years later. He records that he was treating some arthritic patients by auto serotherapy and that one of them who chanced to be a cocaine addict lost his craving after the first two injections—an event that led Modinos to try the same procedure in cases of morphine and heroin addiction. I have now used it in 6 cases and will give brief accounts of all of them.

THE CASES

CASE 1.—Dr A had been taking 3-4 gmn. of morphine a day for two years. He had tried the gradual withdrawal method and had laboratory got down to a bit under gr 2 a day but had failed to reduce the dose any further. He was very anxious to be cured and came to me for treatment in June 1934. After the first 11 treatment injections three days later he felt a further desire for the drug and he went to the central hospital straight although I had told him to stay another week. This was my first case and I was a bit worried that the patient at the remarkable result. He has never relapsed.

ulcer shown in the Registrar General's Decennial Supplement. The one factor common to every type of treatment employed is a diet which includes a high proportion of milk, butter, and fish. Gastric ulcer is notoriously a disease of remissions and relapses such as are characteristic of several deficiency diseases.

It has at all events seemed to me wise to give all patients with ulcer of stomach or duodenum large doses of vitamin A because of the evidence of its great importance in the life and growth of epithelial tissues, and because we are ignorant as to the optimum intake. It is under these conditions that very rapid healing of ulcers has taken place. That unwise therapeutic limitation of diet may be a cause of delay in healing is very likely—it is already known to have given rise to iron deficiency anæmia, and one patient in this series, who, when he was admitted to hospital, was known to have had an ulcer for ten years, was proud of the fact that he had, according to his doctor's reputed instructions, lived during the whole of that time without fresh fruit, vegetables, or meat. I have seen another case in which a severe polyneuritis leading to permanent disability developed after a very prolonged abstinence from meat and fish.

Specific factors apart, all patients with ulcer who have anything less than the full 100 per cent of hæmoglobin require a supply of iron in addition to their diet. Neglect of this factor in treatment may delay cure of anæmia for many weeks, although all hæmorrhage may have ceased. *Provided adequate precautions are observed*, there can be no question that the risks to a partially exsanguinated patient, even on those rare occasions on which it is possible to be certain that all bleeding has stopped, of death from infection in an open hospital ward, or from exhaustion or further loss of blood, are much greater than the possible ill effects of blood transfusion. Personal experience has made me very sceptical of the theory that transfusions of 20 ounces of blood are prone to provoke further hæmorrhage, or to harm the patient in any way. Pygott (1937) points out that in reported cases of death following blood transfusion when blood incompatibility has been excluded, there is reason to believe that the heart or vessels have always been diseased, and that no death has been reported as following the immense numbers of transfusions carried out for hæmorrhage.

SURGERY

My experience of surgical remedies for gastric and duodenal ulcer has been uniformly unfavourable. Particularly does one dread the patient with an ulcer, whether gastric or duodenal, for which any form of short circuit operation has been performed. Even symptomatic improvement is very difficult to obtain in such cases once symptoms have recurred, and one is strongly inclined to attribute initial improvement and subsequent freedom from symptoms, following gastro-enterostomy, to factors other than the surgical operation. Although greater caution is now exercised by surgeons in their selection of cases, and the fashion for wholesale short circuit and excision operations is mercifully on the wane, it is still common enough for a surgeon to consider himself entitled or even obliged to interfere when the diagnosis of chronic ulcer is made. Shelton Horsley, for example, states, "an operation on a gastric ulcer should not long be delayed."

In view of the obvious ease with which cure can almost always be obtained by perfectly safe means, operation for excision of ulcers is, in my opinion, entirely unjustifiable. Initial mortality is great, and the evidence for subsequent freedom from symptoms unsatisfactory, unless, as is sometimes the case, *real attention is paid for years to "medical" treatment after operation*. The removal of such a bulk of tissue, often including that part of the stomach concerned in the manufacture of the hæmaturic principle, is an added danger to the patient.

One is not even entirely convinced that the appreciable mortality, even in expert hands and with local "splanchnic anæsthesia," warrants operations for hour glass deformities and pyloric stenosis unless they are so gross as to exclude the possibility of safe remedies making a tolerable life possible. My impression is that every case in which X rays disclose such deformity should be given several months of "medical" treatment—i.e., rest, physiological diet, and possibly stomach lavage—before operation is considered. The whole of the deformity seen at the first examination is not necessarily permanent.

If one excludes (as recent controversy and personal experience surely entitles one to do) gastrectomy for hæmatemesis as being anything more than a last resort after repeated transfusions have failed to keep pace with bleeding, perforation remains the sole ordinary indication for surgical interference in gastric or duodenal ulceration, and, with the knowledge available, this complication should already be less frequent than it is.

SUMMARY

1 X ray examination of 58 consecutive cases, clinically diagnosed as peptic ulcer, demonstrated the ulcer crater in 55.

2 Gastric ulcer in this series was twice as common as duodenal (a reversal of the commonly accepted proportional incidence). Reasons are given for thinking that the older estimates of incidence were based on a surgical selection of cases.

3 Ulcers known to have been present for at least ten years have been shown to heal in a few weeks under certain conditions, the significance of which, as regards ætiology and treatment, is discussed.

ST BARTHOLOMEW'S HOSPITAL, LONDON.—The governors of this hospital have under consideration a scheme for the erection on a site adjoining the hospital of a special ward block financially independent of the hospital but which would be able to call upon the special services of a large general hospital. This block would be open to persons with incomes of between £250 and £500 whom the hospital by its charter is at present debarred from helping. It is anticipated that the new block would be ultimately self supporting but a capital sum of about £120,000 would have to be found for the building and equipment. No appeal is at present being made to the public but those interested may obtain further information from Sir Gordon Campbell at the hospital.

TUBERCULOSIS IN WILD VOLES

By A. Q. WELLS D.M. Oxon.*

PATHOLOGIST TO THE BUREAU OF ANIMAL POPULATION IN THE UNIVERSITY OF OXFORD

(From the Sir William Dunn School of Pathology)

Griffith (1930) states that tuberculosis in warm blooded animals living wholly in the wild state is unknown. The object of this paper is briefly to report a widespread occurrence of tuberculosis in voles—*Microtus agrestis*. These animals are subject to a cycle of population increasing over a period of three to four years and then decreasing suddenly to a low figure in one or two months (Elton et al. 1935 Findlay and Middleton 1934 Elton et al. MS (in preparation)).

The possibility of this sudden decrease being due to epidemic disease has been the subject of my investigation of which this is a preliminary report.

For the past twelve months the field service of the Bureau of Animal Population in the University of Oxford has enabled me to examine voles both dead and alive from areas in Scotland Wales and England which are uncultivated and fenced off from domestic animals. The Bureau after much experiment has established a system of live trapping and transport of the voles to the laboratory where they have been kept in isolated cages.

On Jan. 20th 1937 a vole died which had been in the laboratory for a little over one month. The post mortem examination showed caseous areas throughout the subcutaneous tissues of the body involving the glands of the neck axilla inguinal region and back with ulceration of the skin round the right pinna. Both lungs contained caseous areas with sharply defined edges; the mediastinal and mesenteric glands were much enlarged and caseous; the spleen was enlarged. The caseous material in the subcutaneous tissues contained a very large number of acid fast bacilli which have the morphology of *Mycobacterium tuberculosis*. The caseous areas in the lungs similarly contained a great number of acid fast bacilli but there was in section very little cellular reaction. Cultures made from the caseous material yielded no growth on nutrient agar but growth was visible after six weeks on Dorset's egg and Petroff's medium. The nature of the growth and the morphology of the organism were similar to that of *Mycobacterium tuberculosis*.

An emulsion of caseous material from several voles similarly infected has been injected either subcutaneously or intraperitoneally into laboratory bred voles guinea pigs and rabbits. The disease has been reproduced in the voles with death of the animals; three guinea pigs have died with widespread disease of the organs, in which acid fast bacilli are present. Large local lesions have occurred in the rabbit without so far causing death. All the guinea pigs and rabbits have become reactors to tuberculin in about one month after inoculation.

Since February 1937 134 voles have been found with macro-copic tuberculous lesion in which acid fast bacilli have been demonstrated. These have been sent from seven different stations in the British Isles. Ninety two of these infected voles have arrived dead or have been killed on arrival. There is therefore no doubt that the infection has occurred in the field and not in the laboratory.

Although some fact about the bacterium in question are not yet known it seems highly probable that it is *Mycobacterium tuberculosis*. If it proves to be so several points of interest arise. The existence of

tuberculosis in wild animals may have some importance in the spread of the disease to man and domestic animals. The use in the laboratory of an animal which naturally contracts the disease may be preferable to the use of the animals used hitherto which are not known to have the disease in nature and the fact that a small animal easily maintained and bred in captivity here is available for epidemiological study may throw some fresh light on tuberculo-

The organism is being typed by Dr A. Stanley Griffith of the Field Laboratories University of Cambridge. I am indebted to him for his advice.

SUMMARY

The presence of disease presumed to be tuberculosis in wild voles is reported. The fact that the disease is widespread in the British Isles suggests that this is not a chance infection.

AUTOSEROTHERAPY FOR DRUG ADDICTION

By MARGARET VINTAS, L.S.A.

DRUG addicts have long been the *bête noire* of the medical profession and it is common knowledge that a long-standing case is an almost hopeless proposition when treated by the ordinary methods of gradual withdrawal or sudden deprivation. In the past I have tried to help many of these unhappy people. Many of them insisted on leaving the nursing home while still needing small doses of morphia and of those that endured to the end the majority sooner or later relapsed because they found themselves unable to cope with their daily work without their accustomed stimulant. These patients are usually the victims of circumstance and I am glad to be able now to record greater success in their treatment.

The method used (auto serotherapy) consists in the hypodermic injection of fluid obtained from blisters raised by applying irritant plaster to the patient's skin the amount injected being usually 5-10 ccm at a time. In the treatment of drug addiction this method was first described I believe by Medinos of Alexandria in 19-0 but I did not see his paper until some years later. He records that he was treating some arthritic patients by auto serotherapy and that one of them who chanced to be a cocaine addict lost his craving after the first two injections—an event that led Medinos to try the same procedure in cases of morphia and heroin addiction. I have now used it in 5 cases and will give brief accounts of all of them.

THE CASES

CASE 1.—Dr. A. had been taking 3-4 grains of morphia a day for two years. He had tried the gradual withdrawal method and had found it of no use to a little under 20 a day but had failed to reduce the dose any further. He was very anxious to be cured and I came to him for treatment in June 1934. After the second 10 ccm fluid injection three days later he felt no further need for the drug and he went home at the end of a fortnight although I had told him to stay in the work. This was my first case and I was at first doubtful of the result but the remarkable result. He has now very relapsed.

CASE 2—Dr B had been taking 4-5 grains of morphia daily for about five years. He had three blister fluid injections and needed no morphia after the second. The only difficulty in this case was insomnia, but at the end of three weeks he was sleeping naturally and felt no desire for morphia. I have lost sight of this case and do not know whether he has relapsed.

CASE 3—Dr C had been taking morphia on and off for the last twenty years, and had taken as much as 20 grains a day. Had been "cured" several times, but always relapsed because he felt ill and depressed after the gradual withdrawal. He needed no morphia after the second blister-fluid injection, but had so strong a desire for a hypodermic injection that I gave him Dionin gr $\frac{1}{2}$ t.d.s., filling up the bottle each time with the equivalent amount of water. When I told him that he had had no morphia for ten days, he ceased to ask for the injections, and left the home after being there three weeks. I have not heard from him since.

CASE 4—Dr D had been taking 3-4 grains of morphia a day for eight years, having started it after an operation for gall stones. Later he developed attacks of pseudo angina, but his supplies of Dangerous Drugs Act drugs were stopped by the Home Office, and he was obliged to seek help in order to be set free from his addiction. He was a difficult patient, threatening to commit suicide unless he could be assured of a supply of morphia for the rest of his life. He had four blister fluid injections, and insomnia was the only difficulty. Finally he left at the end of four weeks, sleeping fairly well with an occasional tablet of Dial at night. I saw him six months later, when he was in good health, had no desire for morphia, and slept well without any sedative. His anginal attacks had ceased. Recently a Home Office official, when writing about another patient, volunteered the information that Dr D is now in excellent health and free of any drug addiction. It is eighteen months since he left the home.

CASE 5—Dr E was a medical missionary who considered it very wrong to take drugs and had tried very hard to cure himself, but without success. He had been taking about 3 grains of morphia by the mouth daily for seven or eight years, and suffered from persistent constipation. After the second blister fluid injection he had no further desire for morphia. Dionin tided him over the first few nights, when he had difficulty in getting to sleep, and at the end of eighteen days he left the home, sleeping and eating normally. I heard from him three months later, and he assured me that he had no desire for drugs.

CASE 6—Dr F had been addicted to drugs for about fifteen years. His daily dose when he came to me was 20-30 grains of morphia, 10 grains of cocaine, and a bottle and a half of whisky. Like most addicts, he had fortified himself with enormous doses the day he arrived, and his first request was for a tumblerful of neat whisky. It seemed a hopeless kind of case, especially in view of the fact that he had been treated a year earlier at a home for nebrates, where it took three months to get him entirely free of drugs. On leaving the home he had remained free for six months although in practice and dispensing his own medicines. What was in his favour was that he seemed genuinely anxious to be cured. After the first 10 c cm of blister fluid Dr F slept and ate well and made no complaint on a daily dose of morphia gr 2 during the first three days. No whisky was given or desired after the first day, and no cocaine was given at any time.

Three days later a further 10 c cm of fluid was injected. For a few days he still wanted hypodermic injections, and asked for them at the usual times, but after the second blister fluid injection, diomn gr $\frac{1}{2}$ was substituted for the morphia without his knowledge. He made no complaint of needing morphia, but had very little sleep the first two nights, even after heavy doses of one or other of the barbiturates. The next night he still seemed excited and sleepless, and so I asked Dr H J A Summons to give him an intravenous injection of Sodium Evipan to ensure a good night's rest. He injected the solution very slowly, giving 20 c cm in all and while Dr F was in the early stage of anaesthesia we gave him strong and repeated suggestions that he should in future sleep without the aid of drugs or spirits. He had about six hours' sleep, and

the sodium evipan in decreasing doses was repeated for a further two nights. Thereafter Dr F slept 6½-8 hours every night without sedative. A third blister fluid injection was given on the tenth day, and from this time onwards the patient declared that he had no need or desire for drugs or spirits. At first he was easily tired and felt disinclined for any exertion, mental or physical, but this symptom disappeared rapidly, and when he left the home at the end of the third week he looked and felt a perfectly fit man.

In view of his past history with the long addiction and heavy dosage, the patient's relatives and I begged him not to return immediately to his work. But nothing that we could say would stop him. He declared that he felt perfectly safe and that under no circumstances would he be tempted to relapse. His wife, however, tells me that he is now taking the same heavy doses as before.

CASE 7—Mr G had become addicted about two years previously through being given hypodermic injections of morphia when suffering from renal colic. He had had various methods of treatment but had always relapsed. He professed a great desire to be set free from his addiction because of the increasing difficulty in obtaining supplies. The result of three blister fluid injections was similar to that observed in the other cases. He had no withdrawal symptoms, and had three nights excellent sleep after the morphia had been discontinued. He ate well and was in excellent health when disaster supervened. One Sunday morning he asked if he might go out alone, saying that he felt that a walk would do him good. Feeling reasonably sure that as a non-medical man he would find it impossible to obtain supplies of morphia in the town, I agreed. I learned later in the day that he had gone straight to a hotel where he had booked a room and summoned a doctor, to whom he simulated renal colic so successfully as to get an injection of a quarter of a grain of morphia. The procedure was repeated with another medical man, who was similarly deceived, but on hearing from the landlord that a doctor had already been called in, he became suspicious and rang up the first doctor, who in turn communicated with me. When Mr G returned late in the evening, tired but pleased with his cleverness, I taxed him with having obtained morphia by false pretences. At first he denied it, but when he saw that I knew what had happened, he took the next train home. He is, I fear, one of the cases that are quite hopeless, for he admitted that he was in no need of the drug when he took all this trouble to obtain it. It is impossible to change a man's character, and the relapse does not alter the fact that he was cured of all physical need for morphia within a fortnight.

CASE 8—Dr H had taken a daily dose of 2 grains of morphia for the past nine years. Recently he had substituted heroin for the morphia and was anxious to be free of his addiction because of an increasing fatigability, and also because he found it difficult to obtain supplies without arousing the suspicion of his chemist. He feared that sooner or later he might get into trouble with the authorities. I immediately replaced the heroin by morphia, as I have found that heroin is far more difficult to withdraw by the ordinary methods than is morphia. Dr H's recovery was uninterrupted and uneventful. After the second blister fluid injection he no longer needed morphia, and a few doses of diomn tided him over the customary period of insomnia. He left the home at the end of three weeks in perfect health and he was wise enough to take my advice and promised to keep away from medical practice until he had been away for six months' holiday. Since then a fortnight has elapsed and he has written saying that he is steadily improving in health and has no desire for any drug.

COMMENT

I hope that these brief notes may induce some of my colleagues to try autoserotherapy in similar cases. It does not perform miracles, but it obviates the usual distressing withdrawal symptoms, such as diarrhoea, restlessness, anorexia, and sneezing, and removes the physical need for the drug within two or three weeks. Naturally, if the patient elects to

return to his addiction after he has been freed from the physical need nothing will prevent him from doing so.

In obtaining the fluid I find two or even three or four small blisters—e.g. $1\frac{1}{2}$ in. square—preferable to one large one because they heal more readily. The fluid is withdrawn before the plaster is removed and reinjected immediately causing no pain or reaction of any kind.

EPILOIA WITH ASSOCIATED TUMOURS OF THE NAIL-BEDS

BY STANLEY G JAMES M.B. Sydney

M.R.C.P. Lond. D.P.M.

DEPUTY MEDICAL SUPERINTENDENT TO THE HAMPTON
STATE INSTITUTION, NEWYORK

EPILOIA is the name given by Sherlock (1911) to a clinical syndrome which consists of mental deficiency, epilepsy, and a condition of the skin known as adenoma sebaceum. Associated with this syndrome is the condition of nodular or tuberoso sclerosis of the brain. According to Tredgold (1929) and others these four conditions—mental deficiency, epilepsy, adenoma sebaceum, and tuberoso sclerosis—occur independently of each other and without anything else, but the presence of the first three together implies the existence of the fourth and the whole warrants wider recognition as a clinical and pathological entity.

CLINICAL PICTURE

Elliott (1936) has recently described a case of Pringle's disease (adenoma sebaceum) with associated tumours of the nail beds of the toes and from a subsequent discussion it appeared that this association, although exceedingly rare, is not unknown. The case which is here recorded is one of epiloia in which the adenoma sebaceum is associated with tumours of the nail beds of the toes as in Elliott's case and also of the fingers. The epiloia is also unusual in that there is mental deficiency with dangerous and violent propensities.

Epiloia is a relatively rare condition. Brushfield and Wyatt (1926) found it in 0.06 per cent. of admissions of mentally defective children to the Fountain Hospital. It is present from birth. A neuropathic heredity can usually be made out and blood relations with atypical moles and hyperkeratosis have been described. The mental deficiency is usually pronounced the lower grades imbecility and idioi being most commonly encountered. The epileptic fits begin at a very early age and are usually of the major variety. Most of the patients die before reaching adult age but this also applies to low grade defectives in general.

THE BRAIN LESION

Sclerosis of the brain associated with mental deficiency occurs in two forms: the diffuse which may be hypertrophic or atrophic and the nodular or tuberoso. The former may be accompanied by epileptic fits but does not enter into the syndrome of epiloia. Tuberoso sclerosis was first described by Bourneville (1880) and a number of cases have since been recorded. The following are some of the authors: Sailer (1898), Tredgold (1903), Dobson (1906), Vogt (1908), Fowler and Carnegie Dickson (1910), Bonilla (1910), Weygandt (1921), Knif (1913), Brushfield and Wyatt (1926), and Ritchey and

Earl (1932). These forms of sclerosis are disorders of development which are present at birth and there are various theories as to their cause. Some writers favour a vascular origin, some an inflammatory and others a neoplastic process, but the majority go no further than developmental anomaly. The sclerosis consists of a neuroglial proliferation which forms tumour masses. In the diffuse form the masses involve the grey and the white matter but in the tuberoso form they are

circumscribed tumours and are confined to the grey matter of the cerebral cortex, the basal ganglia and the retina. In the last situation the tumour known as a phakoma affords direct clinical evidence of the condition of the brain but unfortunately it is extremely rare. The brain tumours are found in the cortex and projecting into the lateral ventricles,

usually in large numbers. They are pale rounded bodies varying in size from a pin's head to a walnut. The consistency is firm even to stony hardness, and in the cortical situation the pin strips move readily from the tumour than from the normal tissue. Central umbilication may occur and cystic degeneration and calcification. Microscopically the masses are seen to be composed of glial fibres and large abnormal glial cells with degenerating glial and nerve cells and myelinated fibres intermingled. There may be thickening of the meninges in the neighbourhood of the tumours.

THE SKIN LESION

Adenoma sebaceum is a papular eruption of the skin. Sequeira (1927) refers to three types: in the first the tumours are pale (Balzer) in the second they are pink (Pringle 1890) and in the third the skin is warty (Hallopeau and Leredde). The eruption consists of neoplasms of the sebaceous glands, the pink colour of the second type being due to overgrowth of the capillary vessels and the third variety resulting from the addition of hyperkeratosis. The tumours are present at birth and at puberty there is either an increase or a diminution in their growth. They are closely set and vary in size from a pin's head to a pea. All three types may be present in the same case. The commonest site is the face, beginning in the naso labial folds and spreading to the nose and cheeks in a butterfly pattern. The pink variety is usually confined to this situation but the others may be found on the forehead, chin, neck, trunk, and limbs. Additional lesions of the skin may also occur and particular mention has been made of cutaneous horns, vascular naevi, vitiligo, white hair in the eyebrows, pigmented and hairy moles, and patches of fibromatous on the trunk, but there is little reference to papillomatosis of the nail beds.

Apart from these skin conditions, tuberoso sclerosis may be accompanied by tumours in the kidney, heart, liver, duodenum, spleen, thyroid, thymus, stomach, and uterus in that order of frequency. For the most part they are myomatous and are not recognizable during life.

CLINICAL REPORT

The patient was a single woman aged 33. She herself states that she suffered from epilepsy, the first seizure when she was a baby and continuing until the age of 2.

FIG. 1.—Photograph showing the white eyebrow on the right side and the adenoma sebaceum.

She left school while in Standard III. She stole her mother's jewellery, sold it, and sent the money in a plain envelope to a friend abroad. The police arrested her as being a person found without visible means of support and she was certified as mentally defective and sent to an institution at the age of 17. She remained continuously in institutions from that time until, at the age of 28, she was sent to Rampton State Institution in 1931. Her propensities as noted in the other institutions were that she was suspicious, unstable, difficult to manage, hostile, violent, influenced others to their detriment, and finally

FIG 2—Filiform papillomata and chronic paronychia around the finger nails

made a violent assault on another patient. She says that she has had warts on her face, body, fingers, and toes as long as she can remember.

FIRST ADMISSION (1931)

Physical state—Height 5 ft 8½ in., weight 12 st 4 lb. Eyes grey, hair auburn. The right eyebrow and the inner half of the right upper eyelashes are white. Palate high and arched. There was generalised adenoma sebaceum with typical "butterfly" distribution on the face, and patches on the trunk and limbs. Numerous warts were present also and there was keratinisation of the finger and toe nails. Apart from some facial asymmetry the other systems were normal.

Mental state—Feeble minded. She was childish in manner, with limited reasoning power and defective mental capacity. Her mental age was below the average for her age. She stated that she had a bad temper which she did not try to control. She was said to be difficult to manage and to be violent and dangerous.

Subsequent progress—A few days after admission she was noted to be hostile in manner and attitude, and she stated that she would knock out the first person who interfered with her. She worked in the laundry in a careless fashion and was usually somewhat depressed. She resented her removal to Rampton and did not realise that she had done anything wrong in the previous institution. She gave no particular trouble except that on one occasion she tore up her bedclothes. Her explanation of this was that she was unsettled because the other girls had made remarks about her personal appearance. Fifteen months after her admission she was sent back to the certified institution, but failed to maintain her progress and was again admitted to Rampton three months later.

SECOND ADMISSION (1933)

Physical state—The previous findings were confirmed, the warts being more fully described as filiform papillomata at the roots of the nails of the fingers and toes. Her general health and condition were moderate.

Mental state—Unaltered.

Further progress—She developed an isolated personality, more solitary and silent than before, objecting quietly to ordinary routine. Six months later she became irritable, insolent and troublesome and needed to be secluded. She attacked the staff when reproved for making a noise. There has been nothing further of note beyond the occurrence of an undoubted epileptic fit, ten months ago.

PRESENT CONDITION

The hair—A considerable number of white hairs are present on the scalp, contrasting sharply with the general auburn hue. The hairs of the right eyebrow and the

inner half of the upper eyelashes on the right side are quite white and contrast with the remainder (Fig 1).

The filiform papillomata—These have given rise to some pain and discomfort and the larger ones have become abraded with secondary infection and haemorrhage. This condition has been treated from time to time by various means, including silver nitrate and tinct. benzoin co., with the result that the appearance of the papillomata is now modified. Those surrounding the finger nails have practically disappeared and there is a condition of chronic paronychia in their place (Fig 2). On the toes they have mostly lost their filiform shape and are more rounded (Fig 3). Patches of small fibromata are also present on the axillary folds and on the neck.

Adenoma sebaceum—The appearance on the face is typical of the Pringle type (Fig 1). The tumours are distributed on the cheeks on either side of the nose in butterfly fashion, some being situated on the nose as well, and a few scattered on the lips and chin. They are numerous and their size is variable, the largest being 7 mm across. The greater part of their bulk is projected above the surface of the skin, their surfaces are smooth and their colour either pink or red. In the other situations on the neck, trunk, and limbs, the appearance of the adenomata is quite different. They are much larger, up to 2 cm across, and somewhat resemble the shrivelled skins of white grapes. They hardly project above the surface and may be felt more easily than seen. Their colour does not differ much from that of the surrounding skin.

The other systems show no abnormality. The ocular fundi are normal and the urine contains no red blood corpuscles. The mental state is unchanged.

COMMENTARY

The outstanding point of interest in the case is the occurrence of fibromata of the nail beds. Fibromata in other parts are common in epiloia, as also are the patches of white hair. Emphasis may be laid on the "grape skin" type of adenomata occurring on the trunk and limbs. These tumours are liable to be mistaken for scars following burns or other injuries, but careful palpation reveals their true nature. I have seen a case of mental deficiency with epilepsy not recognised as epiloia, in which there were several "grape skin" adenomata in the skin over the scapulae, but no tumours on the face. The patient died in status epilepticus and a post mortem examination revealed the presence of tuberosc sclerosis of the brain.

FIG 3—Papillomata on toes

It is to be noted that epiloia does occur with high grades as well as with low grades of mental deficiency. The defect of intelligence is not necessarily obvious and may be overlooked unless attention is paid to the point. Further, the epilepsy may be unknown to the patient or even deliberately concealed. In the case here reported, the history of fits up to the age of eight is rather vague and the diagnosis could not be made with certainty until the typical seizure was observed.

No treatment is known to be of avail in epiloia but the diagnosis of the condition is important in that the expectation of life is thereby considerably reduced.

NUTRITIONAL RETROBULBAR NEURITIS FOLLOWED BY PARTIAL OPTIC ATROPHY

By D FITZGERALD MOORE, M.R.C.S. Eng.
SENIOR MEDICAL OFFICER, WEST AFRICAN MEDICAL
SERVICE, NIGERIA

In 1934 I published a report which included a summary of earlier findings on retrobulbar neuritis followed by partial atrophy due to avitaminosis. The essential symptoms were shown to be defective vision associated with active symptoms or a past history of a sore tongue and sore mouth a scaly itching scrotum and mental and other nervous manifestations.

CLINICAL PICTURE

The history of these patients is quite definite. Vision that has been perfectly normal becomes suddenly misty and there is much difficulty or inability in seeing clearly at a distance and in reading print. There is photophobia in bright light. The patient invariably has or has had one or more attacks of sore tongue white patches at the edges of the lips and dry scaly itchy scrotum. These skin lesions vary in intensity usually the tongue looks raw and the edges of the lips are only slightly cracked, the genital skin being smooth and dry. In worse cases these lesions are intense as shown in the figures. Additionally linear skin lesions may appear on the skin in front of the arms and at the back of the knees. In school-children these lesions are frequently passed unnoticed and their cause is not recognised particularly as they tend to improve in holiday time—that is on return to natural home conditions.

Examination of the eyes reveals no changes externally. In early cases there are few or no fundus changes but very definite changes appear later usually about two months after the first onset. After the first onset of symptoms there is a definite pallor of the disc more extreme on the temporal side. In severer and more advanced cases the disc appears typically that of a primary optic atrophy almost dead white with thin vessels and granular retina. Some very bad cases may also show a true optic neuritis with post neuritic changes. The effect on vision is profound and if untreated lasting even up to an inability to see hand movements. I have met boys at school who listen to their teachers because they can no longer see to read. All the evidence however goes to prove that total blindness does not occur though the patient may be rendered totally unemployable by virtue of his defect.

The optic nerve changes appear to be a direct result of an acute involvement at the onset of the syndrome and its severity is demonstrable in time by the resultant optic nerve changes. The optic nerve condition is therefore a partial post optic atrophy following retrobulbar neuritis.

(Continued from previous page)

The mouth and other skin lesions are not necessarily seen unless the patient is in an early or recurrent stage of the disease probably because he returns home to good food—on account of his illness. These skin lesions are however always a precursor to or concurrent with the first eye symptoms.

Stannus (1911) observed similar skin conditions on the Gold Coast and has always maintained that these were pellagrinous. Scott (1918) described an acute mostly fatal epidemic in Jamaica among the coolie workers in the cane plantations. Sore mouth and tongue defective vision and severe nervous involvement were the main features. Recovered cases showed "residual eye symptoms, high steppage gait &c." There is reason to believe this acute condition has definite points in common with the syndrome I describe though a fatal termination here is unknown. More recently Meagher (1936) appears to have described a similar acute epidemic in the Solomon Islands termed epidemic stomatitis. In 19-0 Wright described in Sierra Leone a disease which he later (1930) termed the A and B avitaminosis of Sierra Leone. The symptomatology is identical with this syndrome. St John (1936) finds an identical condition in the Barbados. He agrees in detail with the cause of defective vision being due to a retrobulbar neuritis followed by partial optic atrophy. Landor and Pallister (1934) reported cases of identical type in Malaya and believe the condition to be a world wide one. In reference to myself they state "he came to the conclusion the disease was due to lack of vitamin B₂ and we think this syndrome must be very near identical with ours." In a recent paper however he blames particular foods also such as *kamava* especially for the defective vision. They agree the ophthalmic defect is a retrobulbar neuritis followed by partial optic atrophy. Recently attention has been drawn to a similar condition in Jamaica by Clark (1937) by a pamphlet on malnutrition as a cause of retrobulbar neuritis in children; and by Dickenson (1937) optic atrophy in children; also in Gold Coast by Purcell (1937). Nicholls (1933) describes a syndrome in Ceylon which is identical in some respects but in which there seems also to be xerophthalmia. Tongue sprue in natives (Manson Bahr 1916) similar in definition appeared to have a dietetic cause.

ETIOLOGY

The disease itself is curable with Marmite alone or with yeast alone the skin lesions by antoclaved products and the eye lesions probably so. Landor and Pallister have proved that liver marmite and both antoclaved marmite and yeast are all successful. Their experiments definitely established that the skin and mouth conditions were dramatically amenable to vitamin B₂ therapy. The visual symptoms were shown to respond in the course of time to liver marmite and yeast on the other hand cod liver oil and fruit juice as controls had no effect on any lesion.

In 1934 cases were quoted in my report showing satisfactory results of treatment. This was given in a combined form—marmite a tea spoonful three times daily with cod liver oil half an ounce daily a standard iron tonic and native palm wine. It was shown that ophthalmological response was excellent in early cases and up to six months quite dramatic end results being obtained. Usually response began three weeks after treatment and improvement was maintained up to a vision of a small Snellen line in a fortnight in the most favourable cases even if they had gone to the point of nearness of vision on the other hand patients with longer history usually over a year responded less well according to the time since the onset of the disease. This was largely in keeping with clinical findings though there were striking exceptions in some apparently fatal cases. I believe however

that absolute cure is not possible, cases seeing only hand movements may improve to 6/6 vision, but there is difficulty in sustained reading of small print, the pupil also appearing to react slowly to light, and photophobia to a slight degree in bright light remains.

This combined treatment was not enough to establish directly the specific cause, and at this stage I believed that it lay between pellagra itself and vitamin B₁ deficiency, plus the probable addition of a toxic factor. During 1935 and 1936 I have carried out as far as local circumstances permitted selective therapy as suggested by Landor and Pallister. Response to marmite, yeast, or autoclaved dried yeast agree fully with their findings. Over 200 selected patients were treated for a period up to 10 months with yeast or marmite alone—the majority with marmite owing to its more stable properties. All skin conditions cleared up rapidly, and the visual response was entirely in keeping with results formerly obtained. Unfortunately I was only able, owing to local difficulties, to use autoclaved dried yeast in 8 cases, which I specially selected for their skin lesions, and treated for a very short time, results here were dramatic. Thus it has not been possible yet for me to prove therapeutically that ophthalmological response is due to vitamin B treatment exclusively, but other general evidence is so strong that I believe this certainly to be only awaiting confirmation in this respect.

To demonstrate the ophthalmological response to marmite I quote a fairly severe and typical case from my records.

A young negro, aged about 19, was seen in July, 1935. Vision was then 4/60. 4/60, he was unable to read. Discs showed well marked atrophic changes. He had a history of one year of sore tongue and mouth, an itching, scaly scrotum, and defective vision. When seen he still had active skin lesions, he had had to leave school because of his defective vision, and latterly had become quite unemployable in any capacity owing to this increasing defect. He was given marmite $\frac{1}{2}$ oz daily for a period of nearly 10 months. His vision had improved in six months to 6/18. 6/12 part, and remained so till I went on leave in November, 1936. The skin condition had cleared up entirely within a fortnight. The whole outlook of this boy is now changed, he is employable, bright, and active mentally, whereas when first seen he was dull and morose.

FIG 1—Photographs showing the condition of the face and of the skin of scrotum and buttocks

The second case illustrates the dramatic effect of marmite on the skin lesions.

A Mende boy from Sierra Leone was brought off an Italian ship by one of the officers who had noted his peculiar gait and appearance. It was possible to keep him only ten days as the ship was leaving port. He was treated by my colleague G. E. Dodds whose notes are as follows: Patient a Mende, aged 30, normal stature, striking facial appearance. Skin dull and rough with symmetrical patches of epithelium round eyes and angles of mouth (Fig 1). Tongue smooth, thickened, pale, slightly denuded of epithelium. Scrotum dry, rugose, and desquamating. Mentally he is slow but able to give his history. Skin condition was present three years. Hands and feet "humbugging" him for some months. Defective vision three years, getting worse, 4/60. 5/60. Illiterate. Severe optic neuritis and post atrophic changes in discs. Knee jerks absent, very ataxic. Kahn test negative. Given marmite $\frac{1}{2}$ oz daily.

Figs 1 and 2 show the remarkable effect in ten days on the skin lesions.

The syndrome is also prevented by adequate proteins of higher biological value. This is demonstrable in prisons in Southern Nigeria, since a carefully controlled and adequately balanced dietary is insisted upon and this syndrome is relatively unknown. On the other hand in institutions where food may not be balanced, particularly in essential proteins, a rate of 10 per cent and over has been observed, quite frequently.

Perhaps this point is best illustrated at a certain school specially visited by me on account of many

cases of defective vision, a number of girls having had to leave school. The school was in an isolated area and consisted of 80 pupils about half of whom were boys. All the girls showed well marked evidence of this syndrome but not one of the boys, whose bright shiny faces showed their good health. All food was brought by canoe twice weekly and distributed equally to both sexes. It was seriously deficient in proteins. Further inquiry showed that the boys augmented their diet daily by the simple expedient of catching and roasting the land crabs that existed in countless numbers in the vicinity. This was not permissible to the girls, who were kept in strict seclusion.

Xerophthalmia, the classical accepted clinical result of vitamin A deficiency,

FIG 2—The same patient after ten days treatment

has not been observed once in all the cases I have seen now amounting to some thousands. This is not surprising since palm oil shown by Prof. J. C. Drummond to be rich in vitamin A is a basic food of these people.

INCIDENCE

There are thousands of these cases some mild many severe. I have seen patients with histories dating back many years who are permanently defective in vision. Some of these patients are now quite old and their history traceable to their old school days the passage of time showing they have got neither better nor worse. I have seen many others whose vision has made them quite unemployable. Some of these are young adolescents and literates and their condition is a tragedy. The onset of defective vision is greater on the literate classes and has thus been specially noticeable in schools. Even so all classes are affected including pregnant women and even very young children.

RELATION TO DIET

The dietary of the Southern Nigerian peoples consists of palm oil *kassava* yams rice green leaves of various kinds local or imported dried fish salt pepper and maize and various fruits in season. Eggs though plentiful are not eaten. There are practically no cattle, and milk is not available in the South owing to the prevalence of tsetse fly. Meat is expensive and a rare luxury to the poor. Tinned milk is popular when it can be afforded. The sea coasts abound in fish but all such indigenous trade is controlled by Africans. There seems little doubt protein foodstuffs afford the missing protective link in this country and their gradual introduction by educational propaganda offers the solution to the prevention of this syndrome. It would be useless to discourage suspect basic foods such as manioc which have been in use for so many generations.

In Barbados St John reports that rice corn flower sweet potatoes locally made biscuit salt pork dried or with butter for flavouring are usually eaten. Eggs and green vegetables they sell rather than eat. *Kassava* they also eat though not as much as formerly. In Scott's polyneuritis cases the diet was almost entirely sugar cane.

TOXIC FACTORS

Clark who also spent 18 months in Nigeria and saw many of these cases who believes that cyanogen bearing foodstuffs such as sugar cane manioc (*kassava*) guinea corn rice millet and maize are by virtue of that content responsible for pellagra in the absence of adequate protective proteins. He believes the essential sulphur of the proteins is eliminated by the cyanogens to form cyanates and that sulphur therefore plays an important part in pellagra. There is much clinically to support the presence of a toxic element plus a deficiency as shown by co relationship to other diseases. There are wide variations in both from true pellagra itself. It is not without interest that Clark informs me from Egypt that he sees many of these pellagrinous cases identical in nature to this syndrome side by side with classical true pellagrins.

I have to thank Sir Walter Johnson late director of medical services Nigeria and Dr. Selwyn Clark deputy director health services for their interest and encouragement. I am also indebted to Dr. A. Clark who showed such keen interest in this work during his visit to Nigeria to Mr. T. Arthur for the preparation of autoclaved bread

yeast and to Mr. G. Duckworth and Mr. P. Phillips for the photographs.

Clinical and Laboratory Notes

UNUSUAL CASE OF CHOKING

By S. SHARMAN M.B. Glasg.

ASSISTANT MEDICAL OFFICER, MANCHESTER HO. HITAL, NOTTINGHAM

A WOMAN of 37 a certified patient with dementia praecox was breakfasting with other patients.

At 8.15 A.M. she suddenly jumped up and hurried to the lavatory (followed by the nurse-in-charge) and while she tried to cough and vomit but merely brought up a little saliva. She then walked to the door leading to the ward garden (about 30 yards) and said to the nurse "let me out I want air." A few minutes later she began to turn bluish, her respirations became gasping, the nurse passed a probang and then brought her back into the ward the patient walking with support. The patient was helped on to a bed where after a few moments she collapsed. Seen 15 minutes later she was ashen grey pulseless and appeared to be dying from asphyxia rather than from apoplexy. Her respirations continued (3 per minute) but gradually despite ear linc stimulants which did not bring back the pulse they ceased and she died at 8.45 A.M.

Post mortem examination showed none of the usual signs of death from asphyxia except that there were a few crumbs of the pudding in the trachea and a slight congestion of that organ. There was some congestion of the lower lobes of the lungs but the upper lobes were normal. The heart was enlarged the myocardium flaccid and pale and there were signs of fatty degeneration in both ventricles. There was marked infarction of the aorta affecting the mouth of the coronary arteries. The whole length of the oesophagus was filled with black pudding and a piece of the skin of that food pressed against the posterior aspect of the larynx took it did not obstruct the airway.

In death from choking the heart beat continues a minute or two longer after the respiratory movements have stopped (Peterson Haines and Webster 1907).—In the present case the entry of air into the

lungs could be clearly heard for some time after the heart sounds were gone

"Where death is due to cardiac inhibition, the usual post mortem findings do not obtain, but these cases are usually characterised by death occurring with extreme rapidity" (Peterson and others, Mann 1922)—In this case death occurred thirty minutes after the first onset of the choking, during which time the patient walked about and spoke a few words

"The impaction of a bolus in the œsophagus caused death from asphyxia by pressure on the trachea in two of my cases" (Smith 1931)—My patient certainly had a large bolus of food in the œsophagus, which may have pressed upon the trachea, but the post mortem findings were more consistent with syncope than asphyxia

"Foreign bodies may by irritation induce a reflex spasm of the vocal cords leading to closure, or the mere presence of such an irritation may reflexly cause syncope, irrespective of the size or character of the substance" (Peterson and others)

In this case it appears that the patient had an attack of choking but managed to free the airway sufficiently to enable her to walk some distance and to speak, that a second obstruction occurred (part of the black pudding skin acting as a valve at that time, or by a reflex closure of glottis due to pressure from the filled œsophagus?), that this also was dislodged or overcome, and then, while air was entering the lungs, that the diseased heart went into syncope, reflexly initiated. At the inquest a verdict was returned that the patient died from syncope due to shock caused by choking

I am indebted to Dr G L Brunton, medical superintendent, for permission to publish this case

EXTRA-UTERINE PREGNANCY

AN UNUSUAL CASE

By R R D KARKI PAHWA, MB St And,
 L M Rotunda

A WOMAN, aged 41, was admitted to the Lady Emerson Seth Chaturbhuy Maternity Home, Amritsar, on Feb 21st, 1937, with a very large abdominal tumour which was diagnosed as ovarian cyst. For confirmation she was twice sent to the Civil Hospital, Amritsar, for radiography, but unfortunately the plant there was out of order and no skiagram could be taken

She had had amenorrhœa since December, 1935, with usual signs of pregnancy such as morning sickness. In the middle of February, 1936, she had slight vaginal bleeding which stopped after two days. In March she had acute pain in her left abdomen lasting an hour. Constipation was severe throughout and her abdomen eventually became so big that she could not get up from bed. In November, 1936, she had another attack of bleeding lasting one day for which she was treated by a leucum. At this time she also felt slight movements in her abdomen on the left side. When she came to the hospital she had had amenorrhœa for 141 months. Three years before the present illness she had had one normal pregnancy and labour

On admission there was a very large abdominal tumour all of fluid giving a thrill. No fetal parts could be felt, but there was a hard fixed lump on the right side of

abdomen just to the right of symphysis pubis. Fœtal heart sounds could not be heard. On March 9th I opened her abdomen under chloroform. A sac with very thin walls and full of fluid came in view. It was adherent to the peritoneum all round, and while I was separating it from the surrounding tissues it burst and 14 pints of blood stained chocolate coloured fluid came out. Then a hand was seen on the right side just above the umbilicus, and I realised that I was dealing with a case of extra

The fœtus and placenta

uterine pregnancy that had gone beyond full term. All the parts of the fœtus were seen, one after the other, and the placenta was found to be adherent to the intestines and to the peritoneum covering the bladder. The fœtus was removed and the placenta was very carefully separated. The abdomen was closed, a drainage tube was inserted, and the patient was put in the Fowler's position as soon as possible

The fœtus weighed 12 lb and was 24 in long, it appeared that it had been dead for some time. The placenta weighed 2 lb and the cord was 17 in long. The fœtus was very well formed (see Figure)

Radiography would probably have led me to make the correct diagnosis, but unfortunately that help was not available. The age of the woman accounted for her amenorrhœa, and therefore the condition was diagnosed as ovarian cyst. The acute pain which she had felt on the left side of her abdomen in March, 1936, was evidently the rupture of her left Fallopian tube, after which the fœtus planted itself on the intestines. I may add that recovery was uninterrupted and uncomplicated despite the fact that there were signs of chronic peritonitis when the abdomen was opened.

Dehradun United Provinces India

ACTION OF TRYPSIN ON DIPHTHERIA TOXIN

By A C BRANDWIJK, M.D

AND

A TASMAN, Chem D

THE question of the preparation of protein free antigens has come very much to the fore of late. After the successful attempts of Avery and Goebel¹, there soon appeared several communications from Topley and his co workers² in which the preparation of almost protein free antigen fractions from various strains of typhus bacteria was described. These latter antigens, which also possessed the property of stimulating the production of antibodies in animals,

appeared to be stable towards treatment with trypsin. An attempt by Stamp and Hendry² to apply a similar treatment to the antigen of hemolytic streptococci was unsuccessful. The antigenic properties were lost during digestion with trypsin.

It appeared to us of interest to investigate whether or not diphtheria toxin would be stable towards the action of trypsin.

The trypsin preparation was prepared as described by Cole⁴ from finely ground ox-pancreas. The alcoholic extract was freed from solid constituents by filtration and had a titre of 1,000⁵ with centrifuged milk. This trypsin extract contained about 25 per cent of alcohol. The diphtheria toxin had an Lf=1/13 while the minimum lethal dose (M.L.D.) was 0.003 c.c.m. 7.5 c.c.m. of the trypsin solution was added to 160 c.c.m. of toxin and the mixture protected against infection by the addition of a little toluene. As a control 7.5 c.c.m. of 20 per cent alcohol were added to 160 c.c.m. of the same toxin and this liquid also covered with a layer of toluene.

After being thoroughly shaken both liquids were kept at room temperature in the dark for five days. After this period the Lf of the control toxin had diminished from 1/13 to 1/115 while the M.L.D. remained unchanged.

The toxin treated with trypsin showed absolutely no flocculation with antidiphtheria serum. Deter-

minations of the V.L.D. with the product treated with trypsin were carried out as follows.

Each of three guinea-pigs were treated subcutaneously with 0.01 0.10 and 1.00 c.c.m. respectively in 4 c.c.m. of saline solution. The first two animals showed no reaction whatever after the injection while the third showed only a slight transient infiltration. This slight reaction may probably be ascribed to non-specific constituents present in the toxin. The product treated with trypsin was no longer toxic.

Thus diphtheria toxin is destroyed on treatment with trypsin. This strongly supports the hypothesis already made by many others that diphtheria toxin is a protein although the possibility of the toxin itself not being a protein at all but a substance very intimately attached to protein cannot of course be entirely excluded.

REVIEWS AND NOTICES OF BOOKS

History of the Acute Exanthemata

By J. D. ROLLESTON, M.A. M.D. FRCP, F.S.A. Medical Superintendent Western Fever Hospital London. London: William Heinemann (Medical Books) 1937. Pp. 114. 7s. 6d.

Dr J. D. Rolleston's work not only fulfils one of the terms of the Trust that the FitzPatrick lectures must, after delivery before the Royal College of Physicians of London be published as a separate book, but as he himself notes serves to some extent as a companion volume to his *Acute Infectious Diseases* (2nd ed. 1929). The author hopes that his book will appeal to the increasing number of readers interested in the history of medicine. Few are better able than he is to judge the extent of this increase which it is to be hoped includes some proportion of those still unqualified. The history of medicine for the qualified provides a study the appeal of which is unending; for the unqualified it should provide this and something more—a sense of perspective. A course of Trousseau and Marchison may still be recommended to the student of the acute infections in particular as a liberal education in the art of clinical observation. Dr Rolleston tells of the history of small pox, chicken pox, scarlet fever, measles, and German measles (enteric and typhus fevers he thinks are more suitably ranked in the class of continued fevers—an obvious opportunity for a second volume of which we trust the author will avail himself at some future time).

As might be expected Dr Rolleston gives a scholarly and most interesting historical account of the diseases he has selected dwelling perhaps more on the clinical than on the epidemiological aspects. The retention of the term "German measles" as a lecture title like the old spelling "Rötheln" where this is chronologically correct is to be regarded as logical in an historical account. From its complete omission Dr Rolleston evidently regards the Illustrious Duke of fourth disease as the Mrs. Harris of the acute infections and this is now the general opinion among those qualified to express one. The

cosmopolitan list of references appended to each lecture is valuable and exceptionally complete. So far as the major acute exanthemata are concerned study of this book and the relevant references should tend to diminish the unwitting rediscoveries of clinical facts already observed and recorded by our medical ancestors.

Einführung in die Allgemeine Biochemie

By Prof. CARL OPPENHEIMER, Dr. Phil. et Med. Berlin. Leiden: A. W. Sijthoff's Uitgeverij maatschappij N.V. 1936. Pp. 22.

THE author explains in a foreword that the book is an attempt to assist biochemistry to its rightful place by developing a general biochemistry that is to teach the fundamental which are not subject to the limitations of division according to the three Kingdoms of the World of Knowledge but are free from any special physiological consideration. He has divided his work into sections under headings such as living matter as a chemical system, the building substances of living matter, synthesis and degradation of foodstuffs and cell matter, the chemical mechanisms of cell processes, and the thermodynamics of living matter; and he deals largely in broad generalisations.

Whether this praiseworthy effort is a success depends on at least two things: first whether experimental biochemistry is yet advanced enough to allow of such a wealth of generalisation, and secondly whether there exist many readers to whose taste this sort of reading is likely to appeal. We ourselves hold biochemistry to be a laborious science in which the thinkers should not be allowed to outstrip the workers, a principle which applies mainly to the biological sciences. Prof. Oppenheimer tends to evade rather than face and overcome difficulties. For instance when he comes to a dangerous topic such as that of carbohydrate oxidation he says at first: "We can give here only quite a superficial picture, for the debated details are interesting only to the expert." But later sums up a situation which

he has not really defined in the facile phrase "In principle, therefore, the vast central problem is to be regarded as solved"

The student is scarcely in a position to appreciate the generalisations, whilst the lack of references would be irritating to the advanced worker who would no doubt prefer the same author's "*Chemische Grundlagen der Lebensvorgänge*"

The Common Neuroses—Their Treatment by Psychotherapy

Second edition By T A Ross, MD, FRCP, formerly Medical Director, Cassel Hospital for Functional Nervous Disorders London Edward Arnold and Co 1937 Pp 236 10s 6d

This book has already proved its value to the practitioner who seeks guidance in the labyrinth of symptoms which neurotic disorders present at every turn Dr Ross makes it clear that he could not hope to help the student to knowledge in a subject beset by theories if he were to concentrate on the difficult issues raised by these theories The book therefore is a practical guide to the everyday problems of neurotic illness rather than a text book on mental dynamics Unlike other departments of medicine in which pathology, etiology, and treatment can be clearly marked off, psychopathology and psychotherapy are closely interwoven It has been wisely said that diagnosis in this department of medicine is only arrived at in the course of treatment when investigation runs concurrently It is for this reason that books of this kind appear to be unsystematic Dr Ross is no ideologist, as his book makes clear, but he is concrete on every page and never abandons his patient to pursue a theory There remain many matters in this volume which will not satisfy the psychopathologist with an eye for systematic study of mental dynamics While Dr Ross admits his debt to Freud, he does not pay 20s in the pound The reader will be grateful to him for a very valuable handbook to the psychopathology of everyday practice

Medical Urology

By IRVIN KOLL, BS, MD, F.A.C.S., Attending Urologist, Michael Reese Hospital, Chicago London Henry Kimpton 1937 Pp 431 21s

THE title of this work is misleading By the term "medical urology" most of us understand those diseases of the urinary system that come under the care of the physician rather than of the surgeon, that is to say, such conditions as nephritis Dr Koll, however, uses the term to imply the urology of the general medical practitioner rather than of the specialist His book is designed to be useful to the general physician and to the medical student It provides a general survey of the subject, and is intended to supply just that knowledge that a practitioner requires without intruding on the province of the specialist Only those methods of examination are given which the practitioner is capable of making and only those forms of treatment described that come within his range of therapeutics For those who want more details a bibliography is supplied

Dr Koll writes clearly, gives the results of his own experience, and avoids confusing his readers with rival theories His book is well arranged and is illustrated by means of excellent diagrams and plates The omission in a book describing methods of treatment that come within the therapeutics of the general practitioner of such subjects as the treatment of urinary infections by means of the

ketogenic diet or of mandelic acid is unfortunate Our impression is that the work will prove of greater use to medical students wishing to revise rapidly their knowledge of urology than to practitioners

Rasse und Krankheit

By Various Authors Edited by Dr med JOHANNES SCHOTTKY, Abteilungsleiter im Stabsamt des Reichsbauernführers Munich J F Lehmann 1937 Pp 408 Price outside Germany M.16 20

A TREATISE on race and disease edited by a German official is likely to excite the apprehensions of a foreign reader, he may expect the virtues of "aryans" and the vices of "non arians" to figure prominently and rhetorically through the 468 pages He will be agreeably disappointed The word aryan is not to be found in the index and, with the possible exception of the concluding article by H Wülker on racial mixture and disease, there is little if anything in the treatise which suggests political prepossessions J Schottky is responsible for a general introduction and the sections on race and mental disease and feeble mindedness O Flössner deals with racial physiology, W Unverricht with race and internal diseases, B de Rudder with race and infectious diseases, G Olpp with tropical diseases, M Schubert with dermatology, B Kihn with neurology, K Beringer with metalues, F Härtel with surgery, G Frommolt with gynecology and obstetrics, W Clausen and R Grimm with ophthalmology, H Barth with diseases of the ear, nose, and throat, F W Proell with odontology, and H Auler with cancer

From the introduction onwards the difficulties of defining race, of distinguishing between racial and environmental influences, and, above all, of securing precise information are emphasised, perhaps even over emphasised de Rudder says firmly that we have no evidence at all of any fundamental differences in the reactions of different races to infectious diseases Kihn says "it is a melancholy fact that all statistical data respecting diseases are thoroughly untrustworthy" Some of the writers make as brave a show as they can with statistical comparisons sometimes of nationalities, as when the marching paces per minute of armies are compared, sometimes of alleged races, the Nordic, the Mediterranean and so on But practically all of them are oppressed by the cloud of doubtfulness in which things are enveloped, even if all are not so gloomy as Beringer who begins his summary with the words "and so ends our journey through the tangle of attempted solutions which overles an apparently so simple question." Some of the writers, for instance Olpp in his article on race and tropical diseases, side track most of the speculative questions and give a straightforward account of what used to be called geographical pathology

The book is very well illustrated and as a text-book of geographical pathology has merits The style of most of the writers is not unduly ponderous and, although a great majority of the references are to German writings, the authors are distinctly aware of the existence of other nations Of course the general problem, like the particular problem which vexed Beringer, is overlaid with difficulties At first it seems so simple, one does not need to be an anthropologist to be confident that, whatever may be the definition of race, we, the Chinese, the African negroes, and the Red Indians, certainly do not belong to the same race How easy it should be to compare their reactions to disease Then we perceive that far from being easy it is very difficult, because, among other things, we have real control

experiments only on a few simple reactions. This is so when we compare what the man in the street would call racial extremes. When we seek to compare Germans, and Frenchmen and Englishmen the business becomes almost fantastic. Perhaps one day some genius will show how the problem may be solved. He is not yet here.

Inhalation Anæsthesia

By ARTHUR E. GUEDEL, M.D. Assistant Clinical Professor of Surgery (Anæsthesia) University of Southern California School of Medicine, London Macmillan and Co. 1937 Pp. 172 10s. 6d.

Dr Guedel says in a short preface that his little book is intended to guide the anæsthetist up to and through his first few general anæsthesias. This slightly ambiguous sentence indicates pretty well the nature of the book. It deals with fundamental principles and makes no attempt to supply that detailed practical information which can really be satisfactorily given only direct from teacher to pupil at the operation table. Nor is the text cumbered with descriptions of apparatus. The book is in fact most interesting to read and unlike the usual small handbook in its constantly scientific outlook and endeavour to establish practice on logical scientific lines. It is more a doctrinal application of physiology to the anæsthetist's aims and activities than a text book and it illustrates the principles which its author has found effective in the education of students. The chart of stages and planes of anæsthesia which Guedel devised and reproduces in the book was made familiar to many British anæsthetists by Dr R. M. Waters on his last visit to this country. In the chapter headed Mechanism of Anæsthetic Requirements the author gives the best account we have come across of the relation between a patient's metabolic rate and the effect which an inhaled anæsthetic will have upon him. He supplies a logical and sensible explanation of phenomena which appear to the uninitiated peculiar and surprising. The second part of the book deals with anæsthetic accidents and here again the strictly scientific analysis of the problems presented is admirable. Throughout there are illustrative cases which are related with a dramatic intensity which is well calculated to enforce the lesson which they teach. We have but one grudge against the author his almost inexhaustible relish in the split infinitive. Many of his pages supply two or three striking examples.

Emanotherapy

By F. HOWARD HUMPHREY, M.D. BRUX. F.R.C.P. F.D.M.R.C. Camb. Honorary Consulting Radiologist to and Member of the Medical Advisory Board of St John Clinic and Institute of Physical Medicine; and EDWARD WILLIAMS, M.D. Glasgow late Physician to the French Hospital, London; Baillière Tindall and Cox 1937 Pp. 188 7s. 6d.

The authors of this book are concerned at the confusion in the mind of the public between the use of radium and its salts as a destructive agent and the exposure of patients to what they regard as the beneficial and innocuous influence of radium emanation in small dosage. In order to mark the distinction and to dispel fears they favour the term emanotherapy for what has been called mild radium therapy or radon therapy. They claim that its value though little appreciated in this country has been recognised by a formidable array of distinguished clinicians abroad, the list including

such internationally famous names as Eiselsberg, Lorenz, Novak, Wenckebach, Sauerbruch and Doederlein. The conditions in which emanotherapy is said to be especially indicated are gout, gonitosis, pelvic pain, salpingitis, sterility in women, psoriasis and chronic catarrh of the respiratory organs and the widespread uses here cited to which this treatment has been put by enthusiasts include mental disease, post-operative adhesions, high blood pressure, neurasthenia, tabes dorsalis, enlarged prostate and spinal arthritis. Most of the readers of this book will remain unconvinced by the argument that the doubtless excellent results obtained by the authors and others in such various conditions depend primarily on radium emanation, whether administered by ingestion, inhalation, subcutaneous injection, in a solution, irrigation or pulverisation. Those who want to acquaint themselves with the methods used by emanotherapists will find them set out in detail and will also be referred to many more special publications on the subject. The book is well produced and printed and the diagrams of apparatus including the inhalation tube partly devised by one of the authors are easy to follow.

Synopsis of Ano-Rectal Diseases

By LOUIS J. HIRSCHMAN, M.D. F.A.C.S. Professor of Proctology Wayne University, Extra Mural Lecturer on Proctology Postgraduate School Michigan, London Henry Kimpton 1937 Pp. 288 15s.

This is a simple practical guide in the treatment of those minor diseases of the rectum and anus that do not require major surgical operation. Almost all the procedures described can be carried out in a well equipped consulting room and for most of them the patient need not be kept in bed. None of the apparatus described is complicated or expensive and although notes on the diagnosis of the more severe affections of the rectum and sigmoid colon are included their treatment is not discussed. The most valuable point about the book is that the description of each form of treatment is so detailed that the reader can picture himself doing the operation. Methods of anæsthesia are particularly well described. The author himself favours caudal anæsthesia but also advocates spinal, sacral and infiltration methods. Inhalation anæsthesia is held to have no place in these minor operations. Some surgeons would prefer gas to infiltration anæsthesia in opening perianal abscesses but Prof Hirschman does not mention it in this connexion. The accounts of the operations for fissure-in-ano and for the removal of piles rob them of much of their terror for the inexperienced operator. The author's special modification of the ligature treatment of piles seems to be particularly valuable in cases where hæmorrhage has so exhausted the patient that the primary consideration is to stop it with as little interference as possible. Prof Hirschman seems to find his ligature operation more satisfactory than injection.

Preparation of the patient for rectal operations and post-operative care of the bowels are described not in a separate chapter but as part of each procedure. Although this involves some repetition it has a practical advantage in emphasising the importance of those stages of the treatment. The chapter on pruritus also contains many useful prescriptions. The volume is profusely illustrated with photographs and line drawings. The author touches for the most part all the methods of treatment included and he deserves praise for his clear and practical exposition.

NEW INVENTIONS

A MODIFIED BRONCHOSCOPE

THE value of direct inspection of the bronchi for diagnosis or therapeutics is increasingly recognised and measures affording improved illumination and an adequate working lumen in a bronchoscope are useful because they minimise difficulties and dangers. The modifications about to be described are mostly those of other writers, but they have been assembled and combined into one instrument with the generous advice and help of Mr Percy G Phelps, of Messrs Mayer and Phelps Ltd.

Fig 1 shows the modified bronchoscope, which can be made in various lengths and calibres. It has been found that for inspection of the main bronchi a bronchoscope of 39.5 cm by 10 mm inside diameter is most useful, for the secondary bronchi an instrument 44.5 cm by 8 mm. permits of an easy and well illuminated view, whilst a tube 48 cm by 7 mm is used for the more distal bronchi. The tube is similar to the Jackson model save that the proximal inch is widened in the vertical axis, so that the inlet of the tube is oval, this facilitates the introduction of endoscopic instruments.

Originally the instrument was equipped solely with the dual projected lighting system as used in the Negus laryngoscopes and oesophagoscopes, and I am indebted to the patentee (Mr R Schranz of the Genito Urinary Manufacturing Co., Ltd) for permission to incorporate this system of lighting. Later

FIG 2

it was suggested by Mr R Doyle, F.R.C.S., resident surgical officer at the Royal Southern Hospital, Liverpool, that the value of the bronchoscope would be enhanced if distal lighting were added, for not only would this increase the illumination for direct inspection of the bronchus, but it would also permit of the use of the Pinchin Morlock telescopes¹ through the instrument. Fig 2 depicts the special holder for use with these telescopes. The dual lighting system is removed and the telescope holder is then fitted into the sockets usually occupied by the dual lighting system. Fig 3 illustrates a telemagnifier as devised by Dr Israel² in the United States. The telemagnifier gives a magnification of $3\frac{1}{2}$ diameters, is light in weight, causes no respiratory obstruction, and can be focused to different distances for use with tubes of various lengths. It is mounted on two rods which are hinged at A near the points where they plug

FIG 3

into the sockets B. These sockets are situated laterally to those for the dual lighting system at the proximal end of the bronchoscope. By means of the hinges the telemagnifier can be tilted instantly out of the field so that instrumentation through the tube can be carried out with the telemagnifier either in position or tilted up as desired.

Fig 4 shows a special upper lobe bronchoscope which is lighted as

FIG 1

described above and which can be used with the telemagnifier. It is designed after the model of Dr Vistreich³ of New York. The dimensions of the bronchoscope are 36 cm by 10 mm and its distal end is cut to form a double V. At the apices of the V is hinged a small stainless steel mirror which is sufficiently large to reflect the entire image of the orifice and proximal portion of the upper lobe bronchus. The angle of the mirror is controlled by a screw mechanism at the proximal

end of the instrument which can be operated easily by the thumb. It is necessary to point out that the interpretation of the mirror image thus obtained requires some practice, but once this technique is acquired the information procured is of great interest and value.

The instruments briefly described above give excellent illumination, they possess a good working lumen, and they can be used either with distal or proximal magnification. They have been in use regularly for two years in a bronchoscopic clinic and have given satisfaction. They are made by Messrs Mayer and Phelps Ltd., of New Cavendish street, London, W 1.

THE LANCET

LONDON SATURDAY MAY 22 1937

THE LONDON BUS DISPUTE

It is regrettable that the comfort and convenience of Londoners and their visitors should have been disturbed during the Coronation festivities by the cessation of their most important means of surface transport but it would be wrong to take the short view that a strike of busmen was a sudden manoeuvre designed to take a mean advantage of a great national event. It was the culmination of years of argument during which there had been constant complaint of stress and ill health due to speeding up of the services as well as frequent lightning strikes at different garages—always against the advice of the men's union and often for apparently trivial causes. General discontent was obvious and equally obvious was the need in the public interest for that discontent to be remedied.

But here comes in a new consideration. If mechanical defects had become troublesome expert assistance would have been sought and laboratory specialists might have advised upon metallurgy or the physics and chemistry of oils just as we believe experts in acoustics were called upon to deal with excessive noise in tube trains but when the human part of the equipment showed signs of stress there seemed to be no awareness of the existence of knowledge that might be applied to the study and alleviation of that difficulty. Ever since the late war forced upon our authorities the need for study of the health and hours of munition workers there has been carried on under the Industrial Health Research Board extensive investigation of these very problems of industrial stress and the methods of meeting it by rest-pauses rearrangement of work or other wise. The results are to be found in the reports of the Board and in addition the National Institute of Industrial Psychology a non official body is at the service of employers and employed for consultation on such matters. Yet evidence at the recent court of inquiry revealed that such questions as whether a certain trip should occupy 108 or 109 minutes whether the extra minute should come off the men's stand off time and whether this was in accordance with the Board's agreement with the union had been a matter of haggle between the drivers' representatives and those of the Transport Board and a cause of exasperation to the men in the district. The logical rights and wrongs of the points concerned are immaterial that the human machinery was in danger of being thrown out of gear was what mattered to the public.

The recommendation of the court that an inquiry should be carried out as to the conditions of work and their effect upon the men is welcome but

the need for the recommendation arouses thought. A recommendation that similar inquiry should be made into financial or engineering difficulties by which the convenience of the public had suffered can scarcely be imagined for the public rightly assumes that such matters are in the hands of experts whose business it is to deal with them. The same public has nevertheless accepted without surprise that a strike is necessary in order to force attention to the human part of the working equipment. We trust that the inquiry will be held for to leave the matter to the issue of a strike is to sow the seeds of further trouble. Industrial psychology is a technical subject and when the claim arose that the men suffered stress physical or mental from driving a modern bus at modern speeds through London streets that claim called for study and perhaps planned experiment, certainly not for a process of bargaining carried out under the threat of a strike. If the general principle involved should come to be recognised as a result of the present conflict we may be saved from worse trouble in the future.

TUBERCULOSIS AMONG WILD FIELD-VOLES

MANY of the most spectacular advances in modern knowledge have taken place when specialists have been forced to look at their own subject from the standpoint of the discipline and technique of some other body's science. This fertile outcome of the interaction of the unlike in science is well illustrated by the announcement by Dr A. Q. WELLS on another page of his discovery of a tuberculous-like disease among English voles. In the foot-and-mouth disease investigation a distinguished animal ecologist Mr CHARLES ELTON has recently been called upon to help in pathological research the co-operation of a pathologist has now been enlisted for the study of some of the special problems of animal ecology being undertaken at the Bureau of Animal Population at Oxford. The early outcome of this co-operation will give satisfaction to both ecologists and pathologists and is a happy augury of a fruitful partnership in the future.

The field or meadow vole (*Microtus agrestis*) widely known as the short tailed field mouse or grass mouse (though it is no mouse) is it will be remembered a little rodent with a reddish brown back and a greyish belly about 4 inches long without its tail and possessed of a blunt head and a short disproportionate tail which looks as if it had been subjected to some untoward accident. The curious little interlacing alley ways or run it makes beneath the meadow grass must be familiar to all who know the countryside. For many years it has been known that this little mammal is subject to remarkable fluctuations in population. Even under average conditions it is very numerous in our meadows though its caution and shyness may give the casual observer a false impression of rareness. From time to time the numbers of these animals decline rapidly and on certain occasions and in certain localities they may almost disappear. They are staple articles of diet for

owls, rooks, and other predatory birds as well as for weasels, and vast numbers are known to be consumed by these enemies, but it has been considered probable that the marked and rapid waning of numbers is due to an epidemic disease and to this condition the name "vole plague" has been given. It is presumably while investigating this cause of mortality among voles, of the nature of which we are quite ignorant, that Dr WELLS has been rewarded by his unexpected and interesting discovery.

The investigations are still at a very early stage, but since February in this year 134 voles have been found with the lesions of tuberculosis and in these lesions acid-fast bacilli were present resembling *Mycobacterium tuberculosis*. In at least one strain the organism has proved virulent to rabbits and guinea-pigs though it is as yet impossible to say whether the prevailing strains are to be referred to the human or to the bovine type of the bacillus. When it is considered that the field vole is extremely common in our pastures and that many of them with open lesions must be scattering infection, the medical and hygienic possibilities of Dr WELLS's discovery become obvious. Whether the bacilli he has found in voles are pathogenic to other animals or to man remains to be seen, but it is noteworthy that they were fatal to guinea-pigs. Obviously the contamination of areas of water supply or of pasture used for feeding dairy herds from this source is a possibility that must at least be considered. In the meantime ecologists, pathologists, and epidemiologists will be equally impatient for further information.

The British voles present exceptional interest in respect to ecology and distribution. Not only does the field vole suffer from "plagues" but at times, by sudden increases in its population, it becomes itself a plague to agriculture and horticulture. Ups and downs in its population are reflected by the ups and downs of owls and other predatory species, the ecologist will have to broaden his stage to make room for such a redoubtable protagonist as the tubercle bacillus and many new problems are bound to arise. Interesting possibilities open in the study of susceptibility among a number of more or less closely allied members of the vole family. Thus there are various sub-species of *Microtus agrestis* which occur upon the heights of the Highland mountains and in the different Hebridean islands and there are at least five different sub-species of the field vole's larger cousin, the Orkney vole, which are peculiar to the different islands of the Orkneys. It will be interesting to study the incidence of the disease and the experimental susceptibility to tuberculosis of these varieties. It may be mentioned that it is generally thought that the Orkney voles (*Microtus orcadensis*) keep their numbers very steady and are not subject to the plagues which affect their relations on the mainland. Not the least instructive of the lessons of this new discovery is that the study of the parasitology of wild life, which has given up so much treasure in the past, is still an unexhausted vein.

MIDDLE-EAR DISEASE IN INFANCY

SPECIALISTS in pædiatrics and in otorhinology have during the past few years become increasingly aware of the widespread ravages of otitis media among very young children, but it is doubtful whether practitioners as a whole have yet grasped the implications of recent observations. The various contributions made to a discussion by the section of otology of the Royal Society of Medicine reported in our last issue bring out clearly the gravity of the situation. Otitis media is evidently extremely common in children under five years old, and the younger the child the more obscure are the symptoms and the more likely is the condition to be overlooked. When suppurative otitis is looked for at post-mortems on children it is very often found and the frequency of its detection in the dead body has very little relationship to the diagnosis of disease made during life. Dr J. H. EBBs in an analysis of autopsies on 880 children mostly under two years old found post-mortem evidence of suppurative otitis in 52.8 per cent and this incidence would be endorsed by most pathologists with wide experience of autopsies on children. It is clear that the clinical diagnosis of the disease in the young is far from satisfactory. Often there appear to have been no symptoms pointing to the ear as a seat of the trouble. Pædiatricians have called attention to the fact that the outstanding symptoms in many children are gastro-intestinal and that a label of "D and V" or "dysentery" may be given to cases which are subsequently, sometimes too late, found to have suppurative otitis as their main lesion. According to Dr T. RITCHIE RODGER, nearly half the cases are bilateral. And the fact that in very young children the tympanic cavity and the mastoid antrum are in such intimate anatomical relationship means that otitis almost necessarily implies mastoiditis.

An exact estimate of the contribution of purulent otitis to infant mortality has yet to be made but it is evidently a factor of considerable importance. Much more information is desirable on the bacteriology of the condition. The general opinion is that hæmolytic streptococci play a major part, but other organisms such as the pneumococci, and even intestinal bacilli, may be implicated. The rôle of the tubercle bacillus under normal conditions is small but significant, tuberculous otitis may on occasions become what amounts to an epidemic disease. Dr R. B. LUXSDEN for example spoke of an incidence of tuberculous otitis reaching nearly 40 per cent in a hospital near Edinburgh. In the light of this information a grave responsibility is placed upon all branches of the medical profession who are concerned with the health and welfare of children. Otorhinologist, pædiatrician, epidemiologist, pathologist, and bacteriologist must pool their experience and collect and correlate more data. In the meanwhile the practitioner must be on the alert to make an early diagnosis, an examination of the ears should be part of the routine examination of every sick child and those who are doubtful of

their ability to interpret what they find should falling expert help err on the side of action. Early incision of the ear-drum it is agreed is a first principle of treatment and this may have to be followed later by a more radical operation.

It is however on the preventive side that constructive action is most urgently needed. From a consideration of general principles comes every hope that this disastrous and crippling disease of infancy is preventable and the problem of the prevention of otitis media and its complications has been and still is largely neglected. The observations of OKELL and ELLIOTT¹ on the spread of streptococcal infection in ear nose and throat wards have made it abundantly clear that infection from patient to patient is a very real thing and is responsible for widespread and as yet probably only partly realised disasters. The investigations of W A BROWN and V D ALLISON² recorded in the current issue of the *Journal of Hygiene* on cross-infection in scarlet fever wards tell the same story. The first and most pressing duty of the practitioner is to realise that otitis media particularly when due to hemolytic streptococci is not only an infective but also an infectious condition and that it should be treated with the same precaution as any other highly contagious disease. The main difficulty of following this precept is of course that the source of contagion may masquerade in various clinical forms. But in cases of established local infection any carelessness or indifference that leads to its spread is a reproach to the whole profession. The limelight has now been turned on a dark corner of everyday medicine and it may be hoped that the report of the recent discussion will serve as a signal for attack from every side on this outstanding problem of child health and welfare.

CLIMATES LARGE AND SMALL

THE medical science of climate still rests on experience rather than experiment. The fashion lately has been to decri the experience to say that all air is the same and any locality as good as another. It is true that man can live at the Equator and (more or less) at the Poles but the fact remains that a journey from one to the other requires physiological adjustments and some people are sensitive enough to notice a difference even in travelling from a Yorkshire moor to a Cornish valley. Nor is this really surprising since life as HERBERT SPENCER put it 'is the continuous adjustment of internal relations to external relations' and even the comparatively crude data of the meteorologist and geographer teach us that our atmospheric environment varies. It varies in time from hour to hour according to pressure temperature wind light humidity precipitation and electric potential not to mention the obscurer influences of atmospheric ionisation or cosmic rays. It varies in place according to elevation soil shelter aspect and vegetation. Some may hold that man provided he has an umbrella is too hardy to bother about such trifles. He can operate

a typewriter or loom equally fast in Bayswater Brighton and Bombay. But can he? And does it make no difference to his output whether his office or factory is at 60° F with an open window or at 70° F with central heating? And even if climatology local and general has nothing to offer the healthy can we doubt that it has something to offer the sick whose powers of adaptation whose sensibility to influences good and bad are notoriously deranged?

As a matter of fact even those most sceptical about climatology already accept much of its teaching. None will deny for example that the activity of micro-organisms and the growth and fruiting of plants are nicely adapted to known conditions of temperature and humidity. From this it is but a step to consider as ELSWORTH HUNTINGTON³ did what is the optimum for the human species. His conclusion (which in a way supports the sceptics) was that there is not so much an optimum as an optimal range since variation rather than stability is favourable to life and the uniformity of a climate is more deadly than its heat. For the development of a high civilisation HUNTINGTON demanded a mean temperature of 64° F a relative humidity of 80 per cent and—equally important—frequent but not excessive changes. Wind and storms are helpful and in this respect the British Isles are fortunate, being situated between three great pressure and weather systems—the high pressures of the Azores the Icelandic low pressures and the continental pressures high in summer and low in winter. But the variation must not be overdone. The unduly stimulant climate has been compared to a bad driver who exhausts his horses whereas the ideal is a rhythmical urging and checking preferring the voice to the whip. How much daily variation should there be in the climate of the factory? How much can be borne by the young adult with rheumatoid arthritis and what are the means round which it should vary?

In our own country the British Health Resorts Association continues its attempt to define the essential features of various localities and its latest handbook⁴ which should be useful to every practitioner takes another step towards scientific accuracy by providing ingenious tables summarising in a few lines the invalid winter to be expected at various resorts. It is right to press for more informative meteorological records of this kind but it is even more important to assess their significance in terms of the human body. Medical climatology—if that is to be its name—must assess the powers of adaptation of the body to climatic influences in youth and old age in health and in illness. Thus conceived it becomes an aspect of medicine which must interest all who seek the efficiency of man and advance is possible in it from many directions. The industrial physiologist with his micro-climates of laboratory

and workshop, approaches it from one angle, the pædiatrician from another, for as BAUDOUIN² remarks, the faulty adaptation shown by many children should throw light on the means of defence against external stimuli and the way they can best be utilised. For many morbid states there is a "climate" which we should seek to promote, and it is almost ridiculous, for example, that at this time of day we should still be uncertain whether children with pneumonia should not after all be nursed out of doors.³ Dr GEORGE DAY⁴ lately mentioned that he was trying to discover the effect of certain types of weather on tuberculous patients and had reached the tentative opinion that they do best when it is positively

vile. Much information on such subjects has been gathered by W F PETERSEN in the United States and published in his "The Patient and the Weather." Hitherto it has been customary mostly to rely on impressions, but better even than the best impressions are *measurements*, and the systematic studies made during the last twenty years on non-tuberculous children in the island of Fohr⁵ near Heligoland are an example of serious effort to introduce precision where it is badly needed. We may be unable to guess whether the "climate" we recommend—be it at the seaside or in a bedroom with closed windows—will benefit our patient, but we should at least try to find out what effect, if any, it has upon his bodily functions and the course of his illness. This is a part of clinical science where we want facts.

ANNOTATIONS

MALARIA AND SYPHILIS

THOSE responsible for the mental hospitals of the London County Council are anxious that the opportunities afforded at Horton for the treatment of neurosyphilis and general paralysis should be better known. A special unit for the treatment of syphilis of the nervous system was established there in 1925 by the L C C and Ministry of Health jointly and some 800 cases have been treated. The unit has served a second purpose, because the malariatherapy given has allowed of valuable studies of induced malaria. The methods developed by the Institute for breeding and infecting mosquitoes have been copied in other parts of Europe. Wagner Jauregg's clinic in Vienna has adopted the Horton technique for examining blood films, and the plans of the insectarium have been reproduced in Germany, Roumania, and Holland. The research on malaria, which has attracted visitors and investigators from all parts of the world, has been made possible only by team work. The cases have had medical care from one of the medical officers of Horton Hospital, the laboratory is in charge of Mr P G Shute with two assistants, the Ministry of Health, besides giving clerical aid, have allowed Colonel S P James, F R S, to direct the malaria work and establish a research centre. Since Colonel James's recent retirement, Horton has formed a liaison with the London School of Hygiene and Tropical Medicine, and Prof J G Thomson is carrying on the work. A whole time investigator, Colonel J A Sinton, I M S, with a malaria research fellowship from the Royal Society, is now at the hospital, and we are glad to learn that another whole time worker, Dr E L Hutton, with a clerical assistant, is undertaking work from the neurosyphilitic aspect, under supervision from Dr W D Nicol, the medical superintendent, who last November visited Wagner Jauregg's clinic as well as hospitals and institutions in Germany. The records of cases already treated will furnish much good material, the incidence of syphilis in families of general paralytics is now being inquired into. The hospital is also keen to treat more and earlier cases, particularly as it is hoped that advantage will be taken of the facilities for treating patients on a voluntary basis at a stage long before the necessity for certification. In this type of case very favourable results are to be anticipated, and the duration of the patients' stay

in hospital should be considerably curtailed, being in suitable cases as short as 3-4 weeks. It is hoped that the opportunities for studying neurosyphilis will attract to Horton as many inquirers as the opportunities for studying malaria have attracted during the past ten years.

SILICOSIS

OBSERVATIONS on the chemistry of some dangerous dusts made by a group of workers at the Imperial College under the leadership of Prof H V A Briscoe and summarised in two letters in *Nature* (May 1st, 1937, p 753) may throw useful light on some of the perplexities of human silicosis. Briefly their discovery is that freshly made dust may be quite different chemically and mineralogically from the rock from which it has been derived: it quickly takes up water from damp air and readily yields alkali and soluble silica on extraction with water, much in excess of the solubility of natural quartz. The same dust when it has lain some time in contact with air is much less reactive, and this accumulated dust has often been used for experiments on animals whereas in actual practice men are of course exposed to dust immediately it has been made by rock drilling or blasting. A natural inorganic particle is so arranged molecularly that, rather like an animal, it is coated with a relatively inert skin, and when it is mechanically broken its molecules are disarranged and it may become by comparison an active chemical agent. It has also been discovered that the solubility of silica from quartz dust is much reduced by mixing with finely divided charcoal, anthracite, ordinary coal, or lime, from which various possibilities in the way of prevention arise as well as some explanation of the difficulties about silicosis in some coal miners.

MUSICOGENIC EPILEPSY

It has long been known that auditory stimuli may bring on epileptic attacks, the commonest form of stimulus being a loud and unexpected noise. Music may, rarely, be a determining cause of fits, and Dr Macdonald Critchley¹ has collected notes of 20 cases illustrating this sequence of events. Of these, 4 were under his own care, 7 were reported to him by colleagues, while the remaining 9 are

¹*Brain*, 1937 60 13

extracted from the literature mostly be it noted of Russian origin. The clinical histories show little in common though it is worth noting that in 11 out of the 16 cases in which it is recorded the age of onset of the epilepsy was over twenty-five years. Dr Critchley is satisfied that the fits showed the usually accepted characteristics of epilepsy and could in no case be classed as hysterical. Often the determining factor could be exactly specified. Thus in one the music must be classical and jazz tunes were ineffective. In another it must be sad or reminiscent in quality. In another only the deep notes of a wind instrument in a brass band would cause the seizure. In another one tune only would be effective. In another only a tune that was unfamiliar; and so on. Perhaps the most interesting part of the paper is an account by a Russian man of letters who was a sufferer from musicogenic epilepsy, of his own sensations and experiences when listening to music. In some of the cases the stimulus was specific. Fits always occurred in response to the music and never in the absence of music, but other cases lacked this specificity. In discussing the pathogenesis Dr Critchley comes to no definite conclusions. He doubts if hyperventilation or variations in cerebral blood-supply are of much importance. He is inclined also to reject the proposition that the phenomenon is a conditioned reflex in the Pavlovian sense, but it is not clear that he has sufficient grounds for doing so. It is recognised that certain emotional states—namely fear or anxiety—may determine fits in one who is already epileptic and surely music may induce a variety of emotional response in those who listen to it. It might be near the truth to regard musicogenic epilepsy as epilepsy in which the fit are a response to one form of emotional stimulus. Consideration of the uncommon but fascinating sequence opens up wide issues.

PERNICIOUS ANÆMIA AND LIVER THERAPY

VARIOUS attempts have been made to deduce from the recorded mortality rates from pernicious anaemia the degree of success that has been attained with treatment by liver in various forms—success that is in the community as a whole rather than in the individual case. It is generally agreed that with an adequate use of liver a fatal termination may be indefinitely postponed in most instances. How far is that objective being attained? Following the introduction of liver therapy in 1920 the mortality rate in England and Wales declined abruptly and has remained at a relatively low level though in late years there has been some tendency for a rise to occur. P. Stocks has computed¹ that since 1920 there has been an average lengthening of life of all affected persons of about three to three and a half years. The decline in mortality has been noted in other countries—notably in New Zealand, the United States, Norway and Canada. In Canada and particularly in Ontario the registered mortality has invariably been high higher according to Hardisty Sellers² than in any other country in the world. This excess cannot he thinks be attributed in any large degree to differences in diagnostic acuity or to medical teaching and its influence on the certifying practice of doctors. Here too however there has been a dramatic reduction in mortality. In 1934 the mortality rates of both males and females were less than half those prevailing in 1911-20. The deaths actually recorded in 1934 numbered 208 whereas if

the death rates at ages in 1921-26 had continued to prevail as many as 562 would have occurred. At ages 30-40 years the mortality in 1934 was only 22 per cent of the rate in 1921-26, at 50-60 it was 36 per cent, but at ages over 70 years the mortality has changed relatively little being 89 per cent of the previous rate. This picture is best explained, as Sellers suggests, by the prolongation of life of persons affected particularly those at the younger ages. In fact, the average age at death of persons certified as dying of pernicious anaemia was 62.1 years in 1926 and 67.7 in 1934. Allowing for the general ageing of the population the average lengthening of life since 1926 is about 5 years. This result it must be noted relates to all cases treated adequately or inadequately and untreated. Sellers notes that it may be regarded as a conservative estimate of the objective efficacy of modern therapy in this disease. It is some measure of the advantage reaped by the community if treated cases alone were considered much greater improvement would doubtless be apparent.

THE OLD ASHMOLEAN MUSEUM

WE add to a recent suggestion in these columns that the present position of the Old Ashmolean is one calling for a sympathy that should take practical form in money. The fine Jacobean building was probably designed by Sir Christopher Wren though it was built by one of those working masons who took a pride in their work. It faces Broad Street is next to the new buildings of Exeter College and is only separated by a pathway from the Sheldonian Theatre. Few know its history fewer still of late years have entered its noble portico and finely lighted rooms. It was built at the cost of the University between 1670 and 1682 to house the collection which Elias Ashmole had obtained from John Tradescant. Ashmole was a man of many parts: solicitor, excise man, freeman, astrologer, botanist, chemist, anatomist, physician, herald, and author of *The History of the Garter*. John Tradescant, traveller and botanist, had a garden in South Lambeth where his name is still perpetuated in Tradescant Street just off the South Lambeth Road. He collected curiosities in many countries and Ashmole, thinking them worthy of preservation, added his own coins, medals, paintings, and the library of J. J. the astrologer. He presented them to a grateful university which caused the house to be built for their reception. The museum was housed in the top floor; the middle floor was used as a school of natural history where lectures were given on chemistry and the basement was occupied by a laboratory with furnaces and a library of books treating of chemistry. Changes took place in course of time. The books went to the Bodleian, natural history specimens were transferred to the new museums in the parks; some of the curiosities to the Bodleian galleries; others to the Taylorian and university galleries. Chemistry was abandoned by the university and was taken care of by the colleges. The Arundell marbles which had long rested against the wall of the Ashmolean found a more suitable home at the British Museum. The old Ashmolean had practically ceased to exist as a museum and was used as a mere adjunct or store for the Bodleian and as a scriptorium for those who were preparing successive volumes of the New English Dictionary.

Then came upon the scene Mr R. T. Cumber, LL.D., an energetic fellow of Magdalen College who set to work on the history of science in Oxford. He soon

found that many scientific instruments, often dating from quite early times, were stored away in the various colleges, and there was enough to form a first rate collection to which generous donors might be invited to add. The idea has already borne good fruit and the Old Ashmolean has taken on new life as a Museum of the History of Science. Its rooms are already filled with instruments, but more space and money are needed. A part of the building is occupied as a scriptorium and some little used books belonging to the Bodleian are stored in the basement. Money is wanted to buy instruments of historic interest which can still be obtained at reasonable prices, to provide cases in which to show them and for many other purposes. Dr Gunther issues an appeal therefore that the Old Ashmolean and its requirements may not be overlooked when the needs of the university are considered in connexion with "The Oxford University Appeal" which is now being circulated. We wish him success very heartily, for at present there is no museum recording the history of science worthy of the name in this country and Oxford is the place where it might well be established and made permanent.

ESTIMATION OF MALE FERTILITY

THE errors incidental to testing male fertility by the examination of condom specimens have long been known. It was these errors that led Dr Max Huhner of New York to urge that examination of the condom contents should be controlled by subsequently investigating specimens taken from the cervical canal after coitus. Returning to this plea,¹ he says that supposed necrospemia has often been due to killing of the spermatozoa by some chemical used in the manufacture of the rubber sheath. In other cases the patient, wishing to keep the specimen warm until its arrival at the laboratory, has placed the container in hot water or in front of a radiator, and the spermatozoa have thus been overheated. Huhner reports cases in which the examination of many condom specimens, with all precautions, has shown that the spermatozoa have died as early as twenty minutes after coitus. Nevertheless in the same cases spermatozoa removed from the female genitalia remained active for several hours under the microscope. He therefore concludes that spermatozoa may preserve their vitality longer in the female genital secretions than in the semen itself.

MENTAL ABILITY IN A RURAL COMMUNITY

AN interesting survey of mental ability in a rural community is reported by the research department of the Royal Eastern Counties Institution, Colchester.² The district selected contained a population of about 1500 and included a small country town. The number of children tested, whose homes were in the district at the time of examination, was 187, but a few were missed because of illness. Of these 187 children 122, or about two-thirds of the total, belonged to one "clan," all of whose members were related by consanguinity or by marriage or by both. The children were divided into pairs according to whether they were related, connected, or unrelated, and the degree of likeness of scores between any two related individuals was compared with that degree which subsisted between any two unrelated individuals. There were altogether 276 pairs of sibs, and the correlation coefficient for them with respect

to intelligence measurement was $+0.30 \pm 0.05$. This figure, the authors point out, is rather lower than that obtained for physical measurement of sibs by Pearson. If, in a random population, mental ability were entirely determined by hereditary factors, the correlation coefficient should lie between 0.41 and 0.50. It is inferred from the relatively low value of 0.30 that other factors besides heredity play a part in the ability to score marks in intelligence tests such as were used, at the same time the correlation is regarded as strongly significant and the investigators have little doubt that in their group brothers and sisters are more like each other than two children taken at random.

The distribution of intelligence was analysed according to paternal occupation. Four groups were distinguished under the general headings of professional men, traders, artisans, and labourers. In the intelligence of the children, there was found to be a steady gradation down these four groups. The children of unskilled labourers were found to have a mean intelligence nearly a third of the standard deviation lower than the general level. It is perhaps to be regretted that the authors did not examine the sizes of the sibships to which the children in these four groups belonged. A survey of the incidence of mental defect was also made. It included not only children but persons of all ages. A high incidence, 1.6 per cent of the total population, was found. Commenting on the magnitude of this figure when it is compared with the corresponding figures for rural areas given in official surveys, the writers suggest that, if strict canons are observed in these investigations, a larger proportion of individuals in rural communities might be counted as defective than has been officially recognised. Mental defect and disorder were also found to occur with greater frequency in the interrelated "clan" than in the rest of the population.

FREQUENCY OF ARTIFICIAL PNEUMOTHORAX REFILLS

Franklin and his colleagues¹ are dissatisfied with the "average" practice of starting a pneumothorax with two or three daily injections and rapidly increasing the interval until air is only given twice or even once a week. This routine method is open to the theoretical objection that during the interval the lung usually expands again, and the pressure to which it is subjected is thus by no means uniform. With this in mind refills were given much more frequently than usual in a series of 65 patients (4 bilateral A.P.) treated between July, 1935, and January, 1936. In some cases air was given daily for several weeks, and the average time before satisfactory collapse of the pulmonary lesion was only 10.4 weeks compared with a previous average of 22. This meant, of course, that the patient's period of disability was much shortened. Two possible objections to the new scheme are mentioned: the first is the additional cost to the patient when the refills are not done in an institution where such treatment is included in the terms quoted; the second is the possibility that the repeated slight trauma to the pleura caused by the passage of the needle may encourage pleural effusions. Effusions developed in 16 (30 per cent) of the 53 cases in which it was possible to induce a pneumothorax, but this figure seems no higher than that found in series treated with less frequent refills. The present paper is published only as a preliminary report and it cannot be decided whether the method

¹ J. Obstet. Gynaec. April 1937 p. 334.

¹ Franklin, R. M., Zavod, W. A., and Percy, H. E., *Amer. Rev. Tuberc.* April 1937 p. 513.

described really represents an advance. It does appear however that frequent refills give more rapid collapse of the lung and the experience so far gained does not suggest that they bring more complications.

LIPIOD PNEUMONIA

It has often been said that Nature contrives new diseases to take the place of those that medical science has controlled. It would seem however that Nature and science manage sometimes to work hand in hand. Thus the new disease known as lipiod pneumonia is as a rule directly attributable to the injudicious use of oily solutions injected into the nose of young infants or to the aspiration of cod liver oil or cream by those that are feeble or rebellious. A considerable number of deaths from this cause have been reported in America since 1926 and these probably represent only a small proportion of the whole. So serious is the condition considered that a brochure about it has been issued to the medical and nursing personnel of the department of health of the city of New York. In this Dr C. F. Bolduan points out that lipiod pneumonia is seen principally in debilitated infants under two years of age and in those with difficulty in breathing or swallowing. In fatal cases the repeated instillation of nasal drops has commonly been followed by repeated coughing or asthmatic attacks and the signs and symptoms of a low grade pneumonia. Where cod liver oil is the responsible agent the pneumonia has usually been more acute. Although complete recovery appears possible the pneumonia often progresses and the infant dies from intercurrent infection. Post mortem the lungs may show the presence of large amounts of oil and changes due to reaction to a foreign body. Dr Bolduan quotes a number of eminent paediatricians on the inadvisability of giving oily nasal drop to young infants. Although the condition is apparently less common in this country than in America the warning is useful.

THE BILBAO CHILDREN

THE HOME Office has given permission for the landing in England of 4000 refugee children from the Basque town of Bilbao. It was stipulated that there should be 1800 boys and 2200 girls, all between five and fifteen years of age and that they should be accompanied by 200 adult women teachers and attendants and 30 priests. The National Joint Committee for Spanish Relief which has made the arrangements sent two doctors and two nurses to Bilbao. The doctors were to examine the children before they went abroad to ensure that no infectious diseases that might involve lengthy quarantine periods were among them. They took medical supplies with them since these are very scarce in Bilbao. The nurses both speak Spanish and have a supply of medical cards which will furnish a medical record for each child; they are travelling back on the ship the Basque steamer *Halana* which has already carried thousands of children to France. The doctors and nurses reported that they had to work very hard under considerable difficulties. Air raids frequently interrupted the work and they were forced to do it from 8 to 12 at night at which time there have so far been no air raids. The *Halana* is expected at Southampton at the end of this week and the children are in the first place being put in a large camp which will serve as a clearing station and a quarantine camp if necessary. This has been erected at North Stoneham near Southampton and is in charge of an admiral's tractor with long experience of such camps.

Damo Janet Campbell M.D. has been assisting with the arrangements in Southampton and is an active member of the committee dealing with this problem. Already 2000 of the children have homes waiting for them, the Salvation Army having offered to take 400 and the Roman Catholic Schools and Homes 1200. The remainder will be accommodated in groups in homes and colonies organised by the National Joint Committee for Spanish Relief. Those who are familiar with the situation of Bilbao will hope that the committee may soon get enough support and offers of help to justify the rescue of more of the children congregated in the town. The address is 35 Marsham street London S.W. 1.

OPIUM ADDICTION

ADDICTION to opium or its derivatives is rare in this country but unfortunately shows a selective incidence on the medical profession since of 630 known addicts in 1935 about 110 were doctors. One of the main difficulties encountered in its treatment is the depression, insomnia and other distressing symptoms that accompany withdrawal and especially rapid withdrawal of the drug. Various means of reducing these symptoms have been tried and on p. 1221 will be found an account of the use of the patient's own serum reinjected for this purpose. Introduced by Modinos in 1929 the method has been gaining popularity in the Orient and Woo² is able to report on no less than 1000 cases thus treated by him and his colleagues at Hong Kong in 1936. Of these 872 smoked opium, 48 swallowed opium pills, 11 took opium plus opium wine, 38 took opium and heroin pills and 33 took heroin pills. He treated his cases as out-patients and no restrictions were put upon them—a severe test for any method. He gave on the average seven injections of blister fluid on alternate days with a total dosage of 18.5 c.c.m. per patient. He says that after the first dose most of the patients found that they needed only half their usual dose and that the drug became definitely distasteful to them after the second or third injection. His criterion of cure was complete abstinence from the drug for a month with improvement in weight and general health, and he reports 16 per cent of cures while a further 18 per cent were able to reduce their dose by nine tenths. Only 24 per cent showed little or no improvement. Various unpleasant symptoms appeared during treatment: the commonest being constipation, insomnia, and epinorrhoea. Black,⁴ writing from Manchuria says that doses as large as 10 c.c.m. sometimes cause a reaction and discomfort and he therefore prefers 5 or 6 c.c.m. while even 1 c.c.m. has an appreciable effect. Schneider⁵ in 1933 had trouble with burst blisters and was led to try boiled milk as an alternative to serum. In assessing the value of these and other remedies for drug addiction we are faced with the familiar difficulty of separating the effect of suggestion from that of the actual method employed—the brilliant results of cathartic use of some form of therapy—especially where as here there is an element of the dramatic—are often followed by the comparative failure of more sceptical workers using the same method. Dr Vivian's cases which were treated in a nursing home under strict supervision showed better

¹ The Traffic in Opium and Other Dangerous Drugs. Report to the League of Nations by H. M. G. Vivian, M.D., in 1931.

² A review of some recent literature of drug addiction by Dr J. W. Adams appears in *Br. J. Med.* 4, 112, 113, 114, 115, April, 1937.

³ Woo, S. W. (1937) *Chin. med. J.* 5, 31, 32.

⁵ Schneider H. (1933) *J. Amer. med. Ass.* 101, 1.

results than did Dr Woo's out patients, and it seems probable that some at least of her success was due to the belief she has acquired in the method and the steady transference of this belief. She wisely points out that "autoserotherapy" cannot cure the tendency towards drug addiction, but it will nevertheless be very useful if it enables the patient, without much discomfort, to get rid of his physical craving. Dr Adams's conclusion¹ about it is that apparently it is "simple and reasonably successful in the case of moderate opium smokers and eaters and does assist withdrawal considerably. It has however its limitations. It is rather painful, it may fail in severe cases and is not very successful where the drug is injected. Also, relapse seems to be as common as with any of the more usual methods."

MEDICINE AND PEACE

MANY feel that if the medical profession, as such, is to help in promoting peace it will do so best by demonstrating the emotional disorders that give rise to war and the means by which nations and individuals may be contented. The Medical Peace Campaign (whose activities are described in our correspondence columns) now has a psychological section, and its bulletin for April contains many suggestions about the kind of action that doctors may fittingly take to expose "false stimulation of the instinct of self preservation." Those who would prefer to read a straightforward statement of one medical man's opinion on the present menacing situation will find it in a pamphlet by Dr J Burnett Rae¹. He writes for the layman, and he writes at the request of a particular body, the Industrial Christian Fellowship, but many of his professional colleagues and many outside the Church will be thankful to see their scattered opinions so well expressed. Dr Rae believes that we shall never prevent war by dwelling on its horrors or by pointing to its senselessness. War is comparable to insanity but in a psychosis even the most absurd delusion has a meaning, the symptoms are a blundering attempt at cure and adaptation. Unfortunately the nations to day are too busy attending to their weapons, or watching those of others, to give more than academic attention to the fundamental causes of war. Dr Rae counters the argument that primitive human communities are necessarily aggressive, and contends that the future is not with those who use their power to trample upon the weak but with those who have a care for them. If we cannot change our nature we can at least change our behaviour. The real solution is not extermination of other people's point of view but understanding of it. At the same time we must be loyal to our own ideals and make them as attractive as possible to the other type of mind. The kind of peace called "non war" is not an end in itself. The peace we seek must be positive.

THE COLONIAL SERVICE

UNTIL recent years, in spite of some abortive attempts at unification, the colonial services consisted of a series of independent and unrelated public services attached separately to each dependency, although under the general coördinating control of the Colonial Office. In 1930 what is known as the Warren Fisher Committee made strong recommenda-

tions in favour of unification and these recommendations were approved by the Colonial Conference of that year and by the then Colonial Secretary, Lord Passfield. The history of the further developments of this policy is set out in a pamphlet (No 475) entitled "The Colonial Service" issued by the director of recruitment at the Colonial Office. In 1932 a start was made by the creation of a unified Colonial Administrative Service with a definite membership, a common method of entry, a general system of training, and a schedule of posts to any of which a member might be appointed. Development has since proceeded by the setting up of other unified branches on a similar plan, a legal service being inaugurated in 1933, a medical service in 1934, and forest, agricultural, and veterinary services subsequently. The introduction of equivalent terms of service in all dependencies is a matter of great difficulty, as allowances must be made for the very considerable differences which exist in climate, cost of living, and the financial circumstances of the various Governments. Considerable progress has, however, been made in a number of colonies towards uniformity in regard to salary scales, pensions, provision for widows and orphans, and the granting of leave and free passages.

The medical service, which at present has some 600 members, including women, offers a wide professional scope. The majority of posts are in tropical Africa and Malaya, so recruits are usually sent for a course at one of the schools of tropical medicine before going out. Later they may concentrate on public health and preventive medicine, departmental administration, a specialty, or research, or on clinical medicine. The appointments are intended to be whole time and members of the service must not count on being able to augment their salaries by private practice, though this is permitted in some stations. There can be no doubt, however, that in its present form the service is one which deserves the serious consideration of medical men at the beginning of their career.

On May 25th and 27th and June 1st at 5 P.M. Dr Edwin Bramwell will deliver the Croonian lectures of the Royal College of Physicians of London. His title will be *Clinical Reflections upon Muscles, Movements, and the Motor Path*.

To celebrate the fiftieth anniversary of the Bassini operation, the University of Padua is publishing two volumes of "Writings on the Surgery of Hernia" containing the original papers of Bassini and contributions to the study of hernia by surgeons in various parts of the world. The Italian Surgical Society has called for June 6th in Padua a special meeting, in the course of which, after two reports on the surgery of inguinal hernia (S Spangaro) and on the surgery of crural hernia (A Austoni) the various problems of hernia surgery will come under discussion. British surgeons wishing to attend are asked to write to the Clinica Chirurgica della R Università di Padova, which will send detailed information.

GLASGOW POST GRADUATE MEDICAL ASSOCIATION—A general medical and surgical course will be held by this association from August 16th to Sept 10th at the Western Infirmary, the Royal Infirmary, and the special hospitals of the city. A number of clinical assistantships will also be available to graduates who wish to make a detailed study of one of the specialties. Further information may be had from the secretary of the association Dr James Carslaw, 9 Woodside terrace, Glasgow, C 3.

¹ Psychology and the Problem of War. By J Burnett Rae M.B. hon. physician for psychological medicine. Croydon General Hospital. Published by the Industrial Christian Fellowship. 4 The Sanctuary, Westminster London SW1. Pp 30. 3d.

It is also prepared from yeast, *aspergillus*, and *rhizopus* and is approximately half as effective physiologically as auxin *a*. The total growth substance content of urine is about 80 per cent auxin *a* and 20 per cent hetero auxin. So far it has not been determined if animals make use of these auxins.

PLANT EXTRACTS WHICH ACT LIKE ANIMAL HORMONES

Cases have been cited by Walker and Janney (1930) in which extractions of male and female catkins, sprouted oats, rhubarb leaves, and yeast produced oestrus in castrated mice. Also Skarzynski (1933) has isolated an oestrogenic substance from female willow catkins, which possessed properties identical with those of trihydroxyoestrin prepared from female urine, for solubility, absorption spectrum in the ultra violet light, and melting point of the acetyl derivative. The plant substance was less active physiologically, containing 1000 mouse units per mg. as compared with 4000 mouse units per mg. of the animal hormone. Butenandt and Jacoby (1933) have also isolated a substance, "tokokinin," from palm nut oil which is chemically identical with α -folliculin, $C_{15}H_{22}O_2$, gives the same rotation for absorption spectrum in the ultra violet light and the same physiological action. Other examples are "glukokinin," which reduces the concentration of blood sugar in a way which is comparable to the action of insulin, and has been prepared by Collip (1933) from yeast, green leaves and roots, and ephedrine, which is chemically related to adrenaline and behaves similarly physiologically.

It is obtained from *Ephedra vulgaris*, a Chinese plant, the stems of which have been used medicinally by the Chinese for five thousand years (Harrow and Sherwin (p. 123) 1934).

It therefore appears that plants produce substances which are analogous to animal hormones and that animal excretions can be used as a source of plant hormones, but it seems doubtful whether the animal body makes use of the auxins which are available in vegetable foods.

EXPERIMENTS WITH OTHER ANIMAL HORMONES

Corresponding botanical investigations on the possible influence of various other animal hormones on plants have been carried out in recent years. Hávás and Caldwell (1935) treated tomato plants and hyacinths with Richter's orchitis extract, Richter's Glandobulin (prolan A), Richter's Glanduatin (extract of the anterior lobe of the hypophysis) and Cortigen (extract of the suprarenal cortex), adrenaline and thyroid extract without showing any marked effect on the growth or flowering of the plants. Glandobulin had a toxic effect on tomatoes. Other workers on the effect of extract of the anterior lobe of the hypophysis are Hykes (1933) who found that opening of leaf buds on dormant branches of certain trees was inhibited by concentrated solution and stimulated by dilute solution of the extract, and that roots of willow and poplar cuttings were longer in the dilute solution. and di Pascal (1936) who found addition of the extract accelerated germination of seeds and that an alkaline extract solution added

to nutrient solutions accelerated growth in some species and had no influence in others. Large doses caused damage to roots and inhibited growth.

For insulin and adrenaline Wasicky (1934) claims an intensification of starch formation from d-glucose in plant cells, and Hykes (1933) found an increase in quantity and size of leaves produced on branches placed in insulin solution, which was greater in dilute solutions. He found that adrenaline in dilute solution accelerated opening of leaf buds and stimulated root growth in willow and poplar, but that concentrated solutions had an inhibitory effect.

Experiments with extract of suprarenal cortex have been performed by three Italian workers—de Gaetani (1929), Occhipinti (1930), and Agostini (1930)—who found that "cortical" stimulated vegetative growth and accelerated reproduction in the water plants, *Lemna minor*, *Azolla corirolana*, and *marisla*.

Thyroid hormone has been tested on bulbs of hyacinth, narcissus, and allium, various species of seedlings, *Lemna minor*, plants of *Aster sinensis*, and branches of various trees. Budington (1925) noted greatly decreased length and increased thickness in roots on narcissus bulbs grown in solution of thyroid extract in water. Microscopic examination showed that the specialised tissues of the root extended nearer the tip in treated roots than controls and he suggested that the precocious development of this tissue was comparable to the precocious development produced in larval amphibia on treatment with thyroid, since new tissues in roots and larvae both originate from unspecialised masses of tissue, the differentiation of which is stimulated by thyroid. Scaglia (1929) noted decreased mass and more rapid development of inflorescences in hyacinths treated with thyroid. Agostini (1930) found little difference in growth of *Lemna minor* or *Azolla corirolana*. Hykes (1933) showed that leaf buds opened earlier when dormant branches were placed in thyroid solution and roots developed earlier on willow and poplar branches than on controls. Chouard (1934) found that branches grew to be 25 per cent longer than controls on plants of *Aster sinensis* treated with thyroxine in solution in water, but no influence was noted on rate of flowering. Davis (1934) treated *Pisum sativum* seedlings with sodium salt of thyroxine in water and culture solutions resulting in shorter, slightly thicker, less branched roots in treated plants but no difference in the green parts. Narcissus and allium bulbs injected with thyroxine flowered earlier but produced shorter roots and foliage. Florentin and Ehrenfeld (1935) have made microscopic examination of roots of *Allium cepa* grown in thyroxine. Less rapid growth was evident at the beginning of treatment which was accompanied by 43 per cent more mitoses in the root cells of the treated plants, than those of controls. This is a similar effect to that described by Budington in narcissus roots. Experiments performed by me (1937) showed that *Phaseolus multiflorus* seedlings transferred from distilled water to solutions of thyroid extract containing 0.1 c.c.m. per 100 c.c.m. distilled water responded by marked decrease in growth in length of root. It was not considered that shoot growth was influenced. Oats and radish seedlings treated with solutions of different concentrations indicated a stimulatory effect to growth of roots and leaves in dilute solutions and an inhibitory effect in greater concentration. When using thyroid extract, in spite of careful sterilisation of vessels used, after several days solutions became contaminated with bacterial slimes and moulds. This condition was also noted by Davis for thyroxine and by Tucker for ketohydroxyoestrin.

Parathyroid hormone was used by me (1937) on oat seedlings. Doses of 2-8 Collip units resulted in shorter length and slightly thicker roots but had no effect on growth of coleoptiles and leaves. A summary of the experiments is given in the accompanying Table.

TABLE SHOWING RESULTS SUMMARIZED

Hormone preparation	Experimental plants	Results
Ovarian—Progynon— β -folliculin β -folliculin	Hyalcinths, lilies, bulbs, seedlings flowering plants, branches	Contradictory—possibly flowering accelerated stimulated growth
Alkaline salt of folliculin	Hyalcinths	Flowering accelerated
Dihydro-folliculin	Hyalcinths, lily of the valley, <i>Aster sinensis</i>	Stimulated growth stimulated flowering
Theobal Ketohydroxy estrin	Bulbs, seedlings cuttings	None toxic
Equiline Equikeline	Hyalcinths and lily of the valley	Stimulated growth greater effect in alkaline solution
Orchitide	Hyalcinth	None
Anterior lobe of hypophysis	Dormant branches of trees	Dilute solution opening of buds and growth in roots stimulated
	Seedlings	Stimulated germination and growth in some species
Prolan A (glands bulbous)	Tomatoes and hyalcinths	Toxic
Insulin	Hyalcinths	Intensified starch formation from d-glucose.
	Branches of trees	In reversed quantity and use of leaves
Adrenaline	Tomatoes	None
	Hyalcinths	Intensified starch formation
"	Branches of trees	Accelerated opening of buds
Suprarenal cortex—cortigen	Tomatoes	None
"cortical"	Water plants	Stimulated growth and reproduction
Thyroid	Hyalcinth, <i>Narcissus allium</i>	Inhibited growth in roots; stimulated mitoses in cell
	Branches of trees	Leaf buds opened earlier
Thyroid Thyroxine Na salt	Seedlings	Inhibited growth in roots.
Thyroxine Na salt	<i>Narcissus</i>	Accelerated flowering
Thyroxine	<i>Aster sinensis</i>	Increased growth of stem
Parathyroid	Seedlings	Inhibited growth in roots

Note.—In several cases dilute solution stimulated growth and more concentrated solution inhibited growth.

Consideration of the results claimed for the influence of animal hormones on plant growth and development shows that some reaction certainly occurs when plants are subjected to treatment. Whether this can be ascribed to definite response by the plant to the hormone in a similar way to the animal response to that hormone is another matter. The results for the follicular hormone are very conflicting but the balance of evidence seems to favour an auxin-like response of increased vegetative growth. The

increased growth after treatment with the pure crystalline substance does not entirely support the theory that the auxin-like effect is due to impurity in the preparation but the evidence for the presence of auxins in animal urine and female hormones in plant tissue makes it seem quite credible that the behaviour of both could be similar physiologically. There are insufficient data to give definite conclusions on most of the hormones but it certainly seems as if the uniformly found effects of thyroid extract can be considered as an indication that it affects plant tissues in a way similar to animal tissues by the stimulation of cell growth by division. This is of particular interest from the botanist's point of view since there is very little definite knowledge of the influence of auxins and other substances upon cell division.

Though much work remains to be done there is already sufficient evidence that the subject is one of importance to medicine, veterinary science and botany. In particular the possibility that the raw materials of some animal hormones may be derived from plants may have to be taken into account in interpreting the symptoms of deficiency diseases.

MEDICINE AND THE LAW

Epilepsy and Workmen's Compensation

Martin v. Finch in the Court of Appeal last month was a workmen's compensation case in which the workman suffered from epileptic fits to the knowledge of his employer. His wife said he had fits fortnightly and sometimes weekly. He worked as a hand drainer. His usual hours ended at 5.30 p.m. but on the day of his death he had been ordered to leave his work at 5 p.m. and take his tools to the field where he would be working next day. A quarter of an hour later he was found dead by the side of his bicycle near the field. The county court judge found as a fact that the workman had fallen from his bicycle in a fit. The deceased had often been attended by a doctor for injuries due to falls from his bicycle which he had to ride every day from his home about four miles away. He had been warned not to bicycle but he had no other way of reaching his work.

The Court of Appeal agreed with the county court that the accident happened in the course of his employment since at the time of his death he was taking his tools under his master's orders to him in a place of work. But the accident to justify the award of statutory compensation must have arisen out

of" as well as "in the course of" the employment In 1933, in *Lander v British United Shoe Co*, the Court of Appeal disallowed the claim where an epileptic workman fell on a floor which was not found to be dangerous There had been a different result in 1905 in *Wicks v Dowell*, where a workman's duty obliged him to work close to an open hatchway He fell into the hold below during an epileptic seizure, and there was an illuminating judgment by Lord Justice Cozens Hardy The employers had argued that the consequences were too remote to make them liable The truer view, said the Lord Justice, is that everybody brings with him some disability It may be disability arising from age or some other drawback An old man is inherently more likely to meet with an accident than a young man, but an employer could not excuse himself on that ground The same consideration applies to a tendency to illness or fits If a man with such a tendency is told to go to work in a dangerous position and there meets with an accident, the accident none the less arises "out of" his employment because its remote cause is to be found in his own physical condition Applying these views of Cozens Hardy, L.J., to the recent case in the Court of Appeal, the Court took account of the facts that the workman had been carrying his tools when he fell off his bicycle and that the employer, knowing of the epilepsy, had let him go off on the bicycle The Court concluded that it was not epilepsy alone which caused the accident, but a combination of the epileptic tendency with the fact that the dead man was placed in an unstable and dangerous position And so the widow is held entitled to compensation

PARIS

A DOCTOR DE FACTO

THE age of miracles having returned, René Hecker entered the French army as an accountant and left it as a doctor After the war he settled in Flavy le Martel where for some 17 years he devoted himself to the care, often gratuitous and always devoted, of the sick Prosperity, the respect and affection of the community from the mayor downwards, and a wife and family—all these things were added unto him Then the Nasta law came into effect with its requirement that all French medical diplomas must be registered in one central office Hecker was invited to conform to this law but could not His credentials, such as they were, proved to be provisional—stop gap army permits to carry on as a surgeon what time he sought original documents lost, stolen, or strayed This spring at Saint Quentin Hecker was prosecuted for the illegal practice of medicine, and for several days he made headline news He was game to the last in spite of a facetious judge and an inquisitive prosecution But the surgeons and physicians he cited as his mentors at Strasbourg in his student days lacked the flesh and blood required of a witness in a court of law, whereas the witnesses for the prosecution who testified to having known him as an accountant were disconcertingly real To create a diversion, he rang the curtain up on his therapeutic achievements Let but his colleagues see him operating or otherwise caring for his patients, and how could they doubt the genuineness of his claims? To which the judge retorted that the question at issue was not his therapeutic prowess but his legal rights to the title of doctor Nothing daunted, Hecker paraded one grateful patient after another, all snatched from the jaws of death, more or less They

were all very pathetic but not quite convincing And in due course judgment was given against the defendant who was fined 1000 francs for the illegal practice of medicine and ordered to pay 5000 francs in damages to the local medical syndicate which had prosecuted him Still refusing defeat, he has appealed against this judgment

VIENNA

(FROM OUR OWN CORRESPONDENT)

KLEIN, ERDHEIM, AND HALBAN

THE medical faculty of the University has lost within ten days three of its most eminent members Prof Solomon Klein, the Nestor among Vienna's medical men, died at the age of 92 while on a visit to Budapest He was well known as one of the best ophthalmic surgeons of his time and as the originator of many new methods of diagnosis and treatment of diseases of the eye He will be remembered with regret by many of the doctors from abroad who visited the ophthalmological department of the Vienna Poliklinik while he was in charge

Prof Jacob Erdheim, the famous pathologist, died suddenly at the age of 63 He was a pupil of Weichselbaum, who early recognised the outstanding qualities of his assistant and gave him every help in his career Erdheim soon became interested in the branchogenous structures He discovered the relation between calcium metabolism, rickets, and the development of the teeth He later began to study the pituitary gland ("Erdheim tumours", adenomata of the pituitary, the hypophysis in pregnancy), and he was also an authority on the histopathology of bones and on the pathology of the blood vessels During the war he studied problems of bacteriology and hygiene His classes were among the best attended in the University and his pupils came from all over the world, attracted by the lucid presentation of his subjects

Prof Josef Halban came from an old Viennese family well known in public life and he himself was intimately associated with the city all his life He studied there, acted as assistant to Prof Schauta, and in 1909 was appointed professor of gynaecology In 1910 he became the director of the gynaecological and obstetrical department of the second biggest hospital in Vienna (Wiedener Krankenhaus) and he held this post until his death A few years ago he was nearly appointed professor ordinarius of the University Clinic but at the last moment his nomination was disallowed because, like Klein and Erdheim, he was of Jewish birth Halban was an original thinker and as long as thirty years ago he had realised the importance of the endocrine glands and had recognised the placenta as an internal secretory organ Indeed, his intuitive and imaginative grasp of the function of the glands was the foundation of the modern conception of hormones He collaborated with Prof Tandler in several well known text books on gynaecology and obstetrics A brilliant but cautious surgeon, he had an enormous private practice, perhaps the largest in central Europe He was a lover of art and music and he married Selma Kurz, the singer

THE SUPRARENALS AND ANGINA PECTORIS

At a recent meeting of the Vienna Gesellschaft der Aerzte Dr Roab reported on a new treatment he has used in cases of angina pectoris Noting the similarity between the symptoms of this condition and those produced by an outpouring of adrenaline into the system, Roab thought it possible that the

attacks are usually attributable to the action of adrenaline secreted in large quantities on a cardiac muscle which has been injured by coronary sclerosis (This does not of course apply to attacks of coronary thrombosis.) Accordingly he attempted to diminish artificially the output of the secretion of adrenaline and especially its excessive secretion by fits and starts. A suitable means of inhibition was found in irradiation of the suprarenal region with X rays. A surface of 8 by 10 cm. on the right and the left side was exposed to 200 r on three consecutive days, 600 r being thus applied over each adrenal gland. (In some cases only one side was exposed daily so that the course lasted six days instead of three.) This very moderate dose nearly always sufficed and the suggestion is made that sufferers from angina pectoris may have adrenal tissue which is abnormally sensitive to X rays, just as the thyroid gland may be hypersensitive in hyperthyroidism. Of the 17 patients carefully observed only 2 showed no improvement after the irradiation and Roab thinks the treatment is worth trial wherever there is no contra-indication. In the ensuing discussion Prof. Schiff pointed out that it would be really worth while to find out whether Roab's assumption—viz. that diminution of the adrenal output is responsible for the improvement—is correct. This can be done he said without resorting to X rays simply by administering ergotamine which inhibits adrenal function. Dr Scherf said he had been working on similar lines but so far his results had not been absolutely convincing. Dr Zimmermann was struck by the fact that only 2 of Roab's 17 patients had hypertonus whereas as a rule half or three quarters of angina pectoris patients have high blood pressure.

IRELAND

(FROM OUR OWN CORRESPONDENT)

RESIDENCE BAR TO MEDICAL APPOINTMENT

It was pointed out in this column on May 8th that the regulation of the Ministry of Home Affairs of Northern Ireland rendering residence in the United Kingdom for five years a necessary qualification for appointment as a dispensary medical officer might result in the exclusion of a citizen of Northern Ireland who had obtained his medical education elsewhere than in Northern Ireland or Great Britain. This has now happened. Last month the Omagh board of guardians by a considerable majority appointed Dr Creivail G. Patton as medical officer of the Omagh No. 2 dispensary district the appointment being subject to the approval of the Minister for Home Affairs. Dr Patton is a native of Northern Ireland who received his medical education at the University of Dublin and as a consequence has been resident in Dublin for the past five years. The Minister has refused to approve the appointment on the ground that by the regulation of 1935 Dr Patton has been compelled to proceed to a fresh election. The several qualifying bodies in the Irish Free State have it is stated drawn the attention of the Northern Government to the unfair discriminations imposed by the regulation against their graduates and licentiates and pointed out that the degrees and licences granted in the Irish Free State are entitled to registration in the General Register and are recognized by the authorities of the various branches of His Majesty's Service—the Royal Navy, the Army, the Royal Air Force and the Colonial Service. It may be added

that many natives of Northern Ireland educated therein occupy important positions in the public medical and other services in the Irish Free State and as candidates for public appointments in the Irish Free State natives of Northern Ireland compete on equal terms with their southern colleagues.

THE LANCET 100 YEARS AGO

May 27th 1837 p 345

From a communication entitled—

GENERAL REGISTER.

WE the undersigned President of the Royal College of Physicians, President of the Royal College of Surgeons, and Master of the Worshipful Society of Apothecaries having authority from the several bodies whom we represent, do resolve to fulfil the intentions of the Legislature in procuring a better registration of the causes of death being convinced that such an improved registration cannot fail to lead to a more accurate statistical account of the prevalence of particular diseases from time to time.

We pledge ourselves, therefore to give in every instance which may fall under our care an authentic name of the fatal disease.

And we entreat all authorized practitioners throughout the country to follow our example and adopt the same practice and so assist in establishing a better registration in future throughout England; for which purpose we invite them to attend to the subjoined explanatory statement in which they will set forth the provisions of the recent statute and the means whereby the important object we have recommended may most effectually be attained.

HENRY HALFORD
President of the Royal College of Physicians
ASTLEY COOPER,
President of the Royal College of Surgeons
J. HIGGSON
Master of the Society of Apothecaries

From an explanatory statement which follows the letter

It is also desirable that such statement should exhibit the popular or common name of the disease in preference to such as is known only to medical men; whenever the popular name will denote the cause of death with sufficient precision.

From a leading article (p 340)

The advice here given is, in our opinion, calculated to detract very extensively from the value of the remarks by which it is preceded. If medical practitioners fall into the loose habit of recording the vulgar names of diseases to the exclusion of their correct scientific appellations in accordance with nosological nomenclature, we shall only obtain from the Registrars a heap of rubbish which cannot be rendered available for any single useful object. Besides it should be borne in mind that the vulgar name of a disease which is of frequent occurrence in one country is unknown to the inhabitants of an adjoining county and terms which are perfectly well understood by inhabitants of the north of England are unknown to the population of the south and the west. Again in the same county when the body wastes or lingers under the operation of some internal chronic malady whether it be of the heart, the lungs, the stomach, the liver or the mesenteric glands the disease when mentioned is generally included under the single designation of "consumption" or "decline." What therefore we would earnestly recommend is this—that the scientific name should never be omitted when the nature of the disease is actually ascertained and that in addition in all cases when the complaint is known by an unlearned appellation the vulgar name should be added to the scientific term. Unless the President of the College give a further notice on this subject containing an additional recommendation, of the tendency which we have here intimated we anticipate that the paper which they have put forth will be productive of very serious and almost irreparable disadvantages.

GRAINS AND SCRUPLES

Under this heading appear week by week the unfettered thoughts of doctors in various occupations. Each contributor is responsible for the section for a month, his name can be seen later in the half yearly index

BY A MEDICAL ECONOMIST

IV

Most of us have heard economics described as "the dismal science." This is certainly a mistake. Economics, to day, is the most exciting science in the world.

Excitement and science, one has been warned often enough, make bad bedfellows. I do not believe it. The gentleman who sprang out of his bath shouting that he had "found it" was certainly excited and so was Pasteur when he hugged the porter in the university quadrangle and imparted to that astonished man the news that he knew at last why tartaric acid crystals might be either dextro or levo rotatory. Ronald Ross, again, was so excited when he found the malarial parasite in the body of a female anopheline mosquito that he sat down and wrote a poem in celebration of the event, and the late James Mackenzie assured me that he experienced a similar feeling when he obtained his first tracings of the auricular wave in the jugular pulse.

These men were excited because, in Mackenzie's phrase, they "knew that they were getting at the truth." Truth must be exciting since, in immemorial promise, "the truth shall make you free." Did not Bunyan's pilgrim shout and dance when the burden rolled from his back? As G. K. Chesterton said on one occasion, England used to be full of the songs and shoutings of happy folk who could not work without rejoicing nor meet one another without making a feast of it. Shouting and singing are heard no longer in English workshops.

Excitement remains, though, in the laboratories where work that is really considerable is being done. And excitement would be spreading from the laboratories to the workshops and factories and the homes of the people if only we knew how to make use of all the good things which science has bestowed, without at the same time snatching work, and the livelihood which depends upon work, from men and women. "Science," laments the good fellow in the street, "has failed. Science can give us only unemployment or poison gas."

It is a monstrous libel, but who shall blame the good fellow? If you invent a method of doing some thing which can be used by one man instead of by the twenty men now employed on the job, you are taking the bread, surely, out of the mouths of nineteen families. That stands to reason and arithmetic. Again if you go on doing that sort of thing often enough there will be trouble, national and international. Poison gas is likely to be wanted.

In other words science is a curse—the greatest man has ever known. Back to the plough, the spade, the bare hands of naked savages grubbing for roots in virgin forests. Away with steam, petrol, electricity, antiseptics, vaccination, inoculation, antitoxins—all the apparatus of modern civilisation and modern medicine. What? Would you preserve life in order that the ranks of the desperate may be swelled? Every child is potential cannon fodder, industrial or military. A baby lost is a living saved.

What balderdash it all is—and what blasphemy into the bargain. Can any science which is probing

this mystery—or rather this black magic—be called dismal while a chance remains that the truth may be found? "The truth shall make you free."

It is all a question of money and not one man in a thousand knows anything about money. Indeed for every person who thinks that money is important in this respect there are ten thousand who think that the real enemy is land or "capital." Land can be seen and capital can be counted. "Would you dispossess the landlords or take my money away from me? Bolshevik!"

* * *

The point about land, of course, is that it can be turned into a monopoly. They grasped this fact clearly and steadily in the Middle Ages and invented a system whereby nobody could acquire an absolute title to land. Kings, not Bolsheviks, instituted this system. It was called the feudal system. From the beginning, noblemen detested it and fought against it, so that they might acquire their land in full possession and thus become monopolists not only of broad acres but also of the folk living upon them. The noblemen of England scored their first great victory over the kings at Runnymede and we therefore celebrate Magna Charta as the foundation stone of our liberty. A second and greater victory was secured when the head of Charles Stuart fell in Whitehall and perpetual alliance of landowner and money lender was sworn over the dismembered body. Charles had refused to borrow from the City of London, he had dared to try to obtain money from the landowners and thus had challenged their absolute titles. It was the feudal system which he had been trying to re-introduce, thank God he did not succeed, for otherwise Englishmen would have not have enjoyed the loss of their common lands nor those great measures of liberation which snatched their acres from the small farmers and transmuted the whole of the yeomen of this land into hired labourers condemned, in the hungry forties, to eat black bread and die of vitamin D starvation.

The destruction of the feudal system was the essential prerequisite of the introduction of the monetary system which is called to day "the credit system." It will surprise many people to learn how this system was discovered.

* * *

There was a man who, long ago, kept a strong room where, for a small fee, you might deposit your gold and silver. He gave you a receipt for the money you entrusted to him. And you, being a child of Adam and lazy, never went back for your gold or silver. These paper receipts, these IOUs, were so much more convenient.

The man who kept the strong room duly noted this fact. Legend says that he was married and that his wife had a quick wit. At any rate, she is reputed to have called her husband's attention to the fact that his receipts were circulating in the town just as if they had been minted coin. The lady drew the correct inferences and gave ear to the serpent. She is reputed thus to have addressed her lord. "They are using your receipts instead of money. They come here for real money only when they are going

on journeys out of the town because in other towns your name is not known. Do you realise that if a man has deposited £100 here he will draw out only about £10 in any year? The lady's husband had realised that quite well. He had observed that about 90 per cent of his stock of gold and silver remained year after year idle upon his shelves. The lady continued. You can therefore issue and lend receipts for ten times the quantity of gold and silver in your keeping without danger of being found out. And it was so. But note that from now onwards the keeper of the strong room was never solvent. Nine tenths of his receipts in fact were receipts for nothing. Day and night the dread lay upon him that all his customers might appear in a body at the same moment to demand their real money. It follows that he did not dare to go into the market himself and buy anything with his receipts. Suppose he had bought a house for £1000. One thousand pounds worth of receipts would now have been in the hands of the buyer who might conceivably present them and ask for his money. Suppose further that on that evil day the value of the house had fallen to £500. It would not be possible in such an emergency to sell the house and so recover from the open market enough minted coin to satisfy the demand.

Now there must be no buying only lending. Then when the borrower brought his house as security for the loan (of receipts for nothing) one could say:

This house is worth £1000. I will lend you £500 so that if prices should fall I shall still be amply covered. But one thing the keeper of the strong room might safely buy outright since its price was fixed and could not change—namely gold. He proceeded to do so and soon he and his friends had bought all the gold in the world with nothing more substantial than their signatures upon receipts for nothing. Gold was money—the only money. They had made a corner in gold. They had secured a monopoly of money. Nothing has ever been bought so cheaply since the world began.

Now the whole world must come and borrow from them seeing that there was no other source of money. The world would be told that security must be given against every loan. Land in absolute title is the best security. The keeper of the strong room and his friends acquired most of the land—also for nothing. The monopoly of money had bestowed monopoly of land and so of all that grows upon or is dug out of the land and of all that is builded upon it. Real stagnation in the face of this terrific fact—for fact it is.

The immense benefits accruing to all of us through the destruction of the feudal system and the ruin

of the kings who were its guarantors can now be understood. Had the feudal system continued land could not have been pledged as security for debt and consequently the monopoly of money must have remained more or less insecure owing to the strength which the feudal system gave to kings and peoples. (There incidentally is the explanation of the fact that the Middle Ages left no debt but many beautiful buildings including the guildhalls and cathedrals whereas our age is likely to leave £8 000 000 000 of debt and much fewer beautiful buildings.) The money lenders had helped the noblemen to destroy the kings so that the noblemen might be free to pledge their land to the money lenders.

When the nineteenth century began all money was a debt to the keepers of the strong rooms who preferred now to be known as bankers. In other words all money consisted of their receipts. You could cash any given receipt for minted gold but had you tried to cash all the receipts on the same day—the thing happened on several occasions. The government always came to the rescue with a moratorium.

Now it is obvious that if all money is debt repayment of all debt would be equivalent to the disappearance of all money. Debt is constantly being repaid to the lenders; it is necessary therefore to secure a constant stream of fresh borrowers—if the truth is not to be made manifest. Men borrow when prices are rising and they hope to make a profit; they borrow also when prices have fallen and they have made a loss. Consequently the system requires an unending succession of booms and slumps. It requires further a solid mass of poverty seeing that people who are well off do not make use of the instalment system and other forms of borrowing. It is the booms and slumps which sterilise all the efforts of science to produce a better world. With a slump in sight the manufacturer will avail himself of every kind of labour saving device—in order to save labour.

But the system has its Achilles heel. If prices or rather the level or average of prices could be held stable borrowing would necessarily cease and the system would come to an end. Thanks to the study of economics undertaken by the President of the United States that is exactly what is now happening. The American level of prices and with it all the other price levels of the world is in process of being stabilised. What is going to happen? Will there ever be another slump?

At least we can say with full assurance that the dismal science is at this moment by far the most exciting science in the world.

PANEL AND CONTRACT PRACTICE

Prescribing for Hospital Patients

THE Somerset insurance committee have been exercised at having to surcharge two insurance practitioners in respect of surgical appliances supplied to patients before leaving hospital. A medical member protesting against the surcharges said that in one case a patient suffering from a disease of the spine underwent an operation in hospital and when treatment there was finished the patient could not be moved without a proper spinal support which was supplied on the instructions of her insurance practitioner. In the second case it was thought that a man's back was broken and the surgeon said that he must have a support before being moved out of the hospital.

At first sight it would appear to be illegal that a patient who can manage to get home can be supplied with a spinal jacket on the order of his insurance practitioner provided it is required for treatment of a fracture of location or disease of the spine while a fellow sufferer who cannot be removed from hospital without the appliance may not be so supplied. But it must be remembered that insurance practitioners are not responsible for the treatment of insured persons in hospitals or similar institutions where they are not open to medical practitioners generally for the treatment of their patient and in fact they exercise no control over the treatment of their patient in hospital. This applies especially in surgical cases where treatment hardly falls within the definition of surgery other than those involving the application of plaster

skill and experience of a degree or kind which general practitioners as a class cannot reasonably be expected to possess. The principle affecting these spinal jackets is surely the same as that applying to drugs, it would not be seriously contended that an insurance practitioner should prescribe drugs for his insured patients in hospital.

In 1931 the I.A.C. issued a statement as an interpretation of the position of hospitals in the matter of treatment of insured persons, with particular reference to the supply of drugs and appliances to such persons. The following extract puts the position succinctly—

If a hospital has a restricted medical staff no insured person is entitled to any treatment at the hospital *qua* insured person, nor is any member of such staff, who is also an insurance practitioner, entitled to treat at the hospital any patient *qua* insured person. It follows, therefore, that the occasion never arises when such a hospital is called upon to dispense, nor any insurance practitioner upon the staff entitled to prescribe *qua* member of the staff of the hospital, medicines or appliances at the cost of the national health insurance funds.

The insurance committee decided to refer the matter to the National Association of Insurance Committees.

Cremation Certificates

An insurance practitioner issued an ordinary death certificate without charge and was then asked for the special certificate required before cremation could take place, for which he rendered an account for a guinea. The relatives raised the question of payment with the local insurance committee, and an inquiry was addressed by them to the Ministry of Health as to whether it was open to the practitioner to submit an account for a certificate required purely in connexion with the cremation. Rule I of the medical certification rules is quite explicit, certificates are required to be given only if they are necessary for the purposes of national health insurance, and the department gave the obvious answer that there is nothing in the rules to preclude a practitioner from claiming a fee for giving a medical certificate in the circumstances indicated.

PARLIAMENTARY INTELLIGENCE

THE FACTORIES BILL IN COMMITTEE

The Factories Bill was further considered by a Standing Committee of the House of Commons on May 5th.

Examining Surgeons

On Clause 119 (Appointment and duties of examining surgeons),

Major NEVEN-SPENCE moved to leave out the proviso that the Secretary of State might authorise a medical practitioner who was employed by the occupier of the factory in connexion with the medical supervision of persons employed in the factory, but was not otherwise interested in the factory, to act as examining surgeon for that factory for such purposes as the Secretary of State might direct. He said the more he looked at that provision the less he liked it. Factory examining surgeons were specialists in regard to knowledge, experience, and qualifications and were, or ought to be, whole-time men at the job. A medical practitioner in charge of welfare work in a factory had not necessarily any of the qualifications which he should have as an examining surgeon. If under Clause 87 (which deals with the duty of an examining surgeon to investigate and report in certain cases) the Home Secretary required an investigation and report in the case of death or injury due to exposure to fumes, or in the case of any disease, that duty should not be carried out by someone who was a paid employee of the occupier of the factory.

Mr WHITE said he hoped the Under-Secretary would give favourable consideration to this amendment. A great deal of anxiety had been felt in some quarters because it seemed to introduce an undesirable principle in doing something which might tend to put the medical practitioner employed in a factory in an undesirable position. Nobody held the medical profession in higher esteem than he (Mr White) did, but people should not be placed in a statutory position where their public duty might conflict with their private interests. Under this clause they might have the position where a man in receipt of a salary of £1000 a year from the occupier of a factory could be appointed, but another who held five shares at a shilling each in that factory would be disqualified from serving. If the Under-Secretary was unable to accept this amendment perhaps he would give special permission for the surgeon employed by the factory to report for certain extra duties.

EMPLOYMENT IN TWO CAPACITIES

Sir J. HASLAM said he hoped that the amendment would not be accepted. He had had experience of factories in which a very high standard had been

developed in regard to the after-care of young people who worked in mills where there was a complete system of medical inspection, nurses, and rest-rooms. In their discretion the owners asked the certifying surgeon to act as their medical adviser in this matter, and who could do it better? The ordinary family doctor had to know something about everything, but the factory inspector became a specialist in his own business in knowing the law, understanding adolescence, and so on. It was a very wise move indeed for those progressive firms who had rationalised their business and set an example to the whole of the country in looking after the health and welfare of their workers, to call in the factory surgeon as their medical adviser not only in regard to certifying but in every other respect of their line. It was a slur on these medical men that they should be excluded by statute from occupying this position and the Home Office would be ill-advised to exclude them from carrying on welfare work in the factories in addition to their ordinary certifying business.

Mr RHYNS DAVIES said that he had come in close contact with this problem, because the factory surgeons had come to see him personally, so that he had heard the case put both ways. He had decided definitely in favour of the deletion of this proviso. Take the case of a young man direct from a university, having passed his examinations as a doctor, who was now employed full time by an industrial firm, and after a year or so applied to become an examining surgeon under the Home Office. In his (Mr Davies's) view it was against public policy, and certainly incongruous, that such a medical gentleman, employed full time and receiving a salary from his employer, should be asked to do a public duty in respect of his own employment. Municipal authorities had decided that once a man was appointed as a full time medical officer he should not do private medical practitioner's work. He did not wish to say anything in criticism of the doctors, who were doing a very noble service, but it was contrary to human nature to expect them to do a public service on the one hand and to do their job for their employers at the same time.

Mr LLOYD, Under-Secretary, Home Office, said it was not easy to make up one's mind on this point. When he first saw this proviso his attitude was that of Mr Rhys Davies, and he was inclined to take the view that it was not right to put any man in a position in which there might be a conflict of duties or interests. Since then, however, he had heard the other side of the question and he was bound to say that it had impressed him. He would remind the Committee that this was only an authorisation to enable the Home Secretary to allow this procedure in certain

cases and for certain purposes and therefore it could be closely controlled by the Home Office. Most of these factory doctors were very keen on their job. It was in relatively progressive industries that the employers had been sufficiently public spirited to go to the trouble and expense of having a special doctor for this purpose. That was a development which the Home Office would like to encourage. It would seem that it was not necessarily right always to forbid definitely a works doctor who knew so much about the conditions in the factory from performing some of this work under the Factories Bill, such as for instance the certification of the fitness of young persons. Other people might take a different view but he thought that under the safeguards provided in the Bill the Home Secretary might have power to authorise this. He agreed that if it were authorised improperly it might be liable to abuse but on balance he thought it was wise to retain this proviso in the Bill.

Mr RHYSDAVIES asked what was the process whereby an examining surgeon might be removed from the list if it was found that in the public interest he should not continue with his work.—Mr LLOYD: I am taking a little advice on that matter.

POSSIBLE CONFLICT OF INTERESTS

Mr SILVERMAN said an examining surgeon was called upon to act in a quasi-judicial capacity and to do things in which there might be a conflict of interests not between the doctor and the public but between the employer and the employee. Under Subsection (4) of the clause under discussion it was provided that the examining surgeon of any factory should have power at all reasonable times to inspect the general register of the factory. In Subsection (6) of the clause it was provided that an examining surgeon should if so directed by the Secretary of State make special inquiry and examination of employed persons as might be directed. Frequently a special inquiry would be required when there was a suggestion that something improper had occurred or where there had been a breach of the regulations. In such a case a doctor who was an employee of the factory would take part in something of the nature of a judicial inquiry. Subsection (9) of the clause stated:—

References in the Workmen's Compensation Act 1926 to a certifying surgeon shall all be construed as references to an examining surgeon appointed under this section and references to the certifying surgeon for the district in which the workman is employed shall in a case where a workman is employed in a district for which no examining surgeon is appointed be construed as references to the medical practitioner (if any) appointed by the Secretary of State to have the powers and duties of a certifying surgeon under Part II of the Workmen's Compensation Act, 1926.

There the duties were almost absolutely judicial. There were many cases of industrial disease where it was the business of the certifying surgeon to certify what disease had been contracted and whether it had arisen out of the employment. In many cases the certifying surgeon's certificate was conclusive or almost conclusive as to the right to workmen's compensation. If a certifying surgeon was given powers to decide people's rights as between employer and employee it was not proper that he should be a person employed by the employer against whom the rights were being determined. It was not suggesting, that doctors in that position would act improperly, but the policy of the law had always been not to place in positions of judicial office or quasi-judicial office persons who were in any way bound to either side in the matter which was being litigated. He did not say that the Secretary of State would often appoint persons where Subsection (9) would have to be operated but surely it was much safer on the whole not to have this proviso in the Bill at all.

Mr SMITH said that he found as many members of the Committee did some difficulty in reconciling

this proviso with the provisions of Clause 87 of the Bill. He suggested that the Home Secretary might insert some words by which while it would be possible for a paid medical officer of a particular factory to be an examining surgeon, he would not be permitted to investigate the cause of death or of some disease reported by the Inspector which occurred in his own factory but some other examining surgeon would be called in to do that class of work.

A HOME OFFICE AMENDMENT

Sir JOHN SIMON, Home Secretary, said he rather liked that suggestion. There were undoubtedly cases in which according to general notions of what was fair and right it would not be proper for the medical officer of a factory to act as between possibly contending parties. On the other hand as a matter of common sense and progressive administration it would be a pity if a factory medical officer appointed by a progressive factory owner to look after his work people's health were debarred from certifying who was fit and who was not fit because that work depended on a man's knowledge of the people and their work. He (Sir J. Simon) would be prepared to amend the proviso so that it would run something like this: "Provided the Secretary of State may authorise a medical practitioner to act as examining surgeon for that factory and instead of saying 'for such purposes as the Secretary of State may direct' it might be sufficient to say: 'for the purpose of examining and certifying the fitness of young persons'."

Mr WHITE: There is also the matter of certificates of employment.—Sir J. SIMON: Yes; it arises under Clause 92. Continuing the right hon. gentleman said that if he might put the words he had suggested into the Bill provisionally he was willing to do so.

Major NEVEN SPENCE withdrew his amendment and moved an amendment in the form suggested by Sir J. Simon which was agreed to.

Mr RHYSDAVIES moved an amendment providing that subject to the consent of the employed person concerned the examining surgeon should have the right to inspect the medical records of the medical practitioner employed by the occupier of the factory.—Mr LLOYD said the Home Office would like to go into this matter further and see whether the proposed amendment was desirable.

The amendment was withdrawn.

THE QUESTION OF SCHOOL MEDICAL DOSEMIERS

Mr ELLIS SMITH said that there had been gradually growing up an ideal system of medical supervision of school-children up to 16 and 16 years of age. The medical men and women who were administering the Education Acts had scientific knowledge of the development of the children, kept records of their health and capabilities in the classes and were in constant touch with the children themselves. Up to the age of 16 the future of young people was very uncertain. In these times of repetition work in large factories it was common for young people to be discharged at 16 or 17 years of age and the progressive education authorities were of the opinion that the medical officers who administered the Education Acts ought to have jurisdiction also over the children until they reached the age of 16. He understood that the medical officers were already responsible for children up to 16 so far as the elementary schools were concerned and in the case of the secondary schools they were responsible for them until the age of 16. He asked the Home Secretary before the Report stage of this Bill to reconsider the whole of this clause in order that this gradually developing scientific method of handling children up to the age of 16 might be continued until they were 18.

Mr LLOYD said of course the view of education is on a matter of this kind and it was not strictly within their purview, were not the final word; there was another side. There were also the points of view of the industrialists and the doctors to be taken into account and they were not quite the same thing.

Everyone knew that doctors attached great importance to a proper medical history of a case, and they were really at a loss if they had not got it. If it were necessary to change the provisions of the Bill in order to make sure that these medical histories would be available, and if they could not be made available in any other way, the case would be very strong, but even then there would be considerable objections. He believed that quite a large number of school-children—many more than one was inclined to think at first sight, indeed he had heard it estimated at 50 per cent, though that could not be true in all cases—went to work in areas different from those in which they had grown up as school-children and that would make the working of this scheme, if it was still to be based on the educational medical system, rather difficult. In any case, however, he thought they must realise that these medical histories could be made available. There were elaborate provisions in Subsection (9) of Clause 92 for making available those medical histories which were really important. Therefore he did not think that the case was so strong as was suggested, and he did not think

that they ought to take the view that the doctors under the education system were more likely to do the work better than the examining surgeons were doing it to-day. They were practical doctors who had had considerable experience of industry, and he thought that the Committee would be ill advised to make such a change as had been suggested.

The clause was ordered to stand part of the Bill.

FEES OF EXAMINING SURGEONS

On Clause 120, Mr. VIANT moved to provide that the Home Office should be charged with the expenditure in connexion with this part of the Act.—Mr. LLOYD said he thought it was a reasonable view to take that these medical examinations were on a similar basis to the other precautionary measures which occupiers were required to take, and of which they had to bear the expense and he saw no reason why they should be relieved of this particular expense. The amendment was withdrawn and the clause was ordered to stand part of the Bill.

The Committee adjourned until May 25th.

CORRESPONDENCE

OBSTETRICS IN GENERAL PRACTICE

To the Editor of THE LANCET

SIR,—I am in agreement with your leading article of May 8th that the proposals contained in the recent report by the Ministry of Health on maternal mortality and morbidity are revolutionary. You leave one doubting, however, whether you approve or disapprove of the revolution. On balance, I conclude that you approve, as I do. For many years I have advocated the recommendations contained in the report. To put it very simply, operative obstetrics should be placed on a plane with surgery and the surgical specialties—only experts should deal with it. By experts I include not only pure obstetric specialists but those general practitioners who, by post graduate training and the interest they take in obstetrics, have qualified to practise this special branch of medicine and surgery.

My criticism of the report is that it does not define and detail how the obstetric service is to be organised. I did so in 1931 and included my scheme in "Maternal Mortality and Morbidity: a Study of their Problems" published by E. and S. Livingstone in 1933.

We are now going to have expert municipal midwives. Their work should be directly associated with the antenatal clinics of local authorities, this would give those centres very definite supervision of their work and lessen the number of "inspectors," or "supervisors" as the Minister of Health prefers to designate them, necessary for the service.

The medical staff of the antenatal clinics should be well trained and experienced obstetricians and they should act as consultants to the municipal midwives when they require advice or assistance. Further, the obstetricians of the antenatal clinics should be on the staff of the local maternity hospitals and act as assistants to the medical director or directors of the hospitals. At present in many antenatal clinics of local authorities the medical staffing is unsatisfactory, because the individuals doing the work are engaged only in the antenatal care of pregnant women—they have nothing to do with the supervision of women in parturition or during the puerperium.

In many large cities, and certainly in all in which there is a teaching school, pure obstetric specialists are to hand. In some these would have to be intro-

duced, as has been done in a few instances. In small cities and towns specially well trained family practitioners should be enlisted into the service. It is unfortunate in some respects that obstetrics is common with so many other departments of medicine has to be removed from the province of the family practitioner. But as you point out "occasional obstetrics is even more dangerous than occasional motoring", possibly "may be" should be substituted for "is".

One word more. I think it would be preferable if in the further developments of the service construction were made from the centre or the institution rather than the periphery. It is impossible to predict to what extent institutional treatment may extend. As a simple example—a number of us think that all primigravidae should receive institutional treatment in their first confinement.

I am, Sir, yours faithfully,

Canterbury May 13th

MEDICAL PEACE CAMPAIGN

To the Editor of THE LANCET

SIR,—The death early in April of Dr Cecile Booyesen, the secretary of the Medical Peace Campaign, has been a great loss to her colleagues. It was chiefly through her inspiration and energy that the work of such a campaign was conceived and initiated. As we, who were closely associated with her, interpret her thought, it was that our profession has a duty to strive for the prevention of all human suffering and pain by penetrating to their causes and removing them. If war came to be outside the medical purview, one of the main sources of such suffering would be eliminated. A calm, scientific approach is needed and the profession as a whole should be urged constantly to debate the problems associated with war and its causation much as it debates the aetiology and prevention of disease.

It is in this spirit that her work will be carried forward. We do not anticipate spectacular results, for the point of view will require discussion among our colleagues before it is likely to receive full acceptance. But primarily it is this discussion that we wish to initiate and foster.

An account of the activities of the Campaign up to date will be found in the three bulletins that have so far been issued, but we feel that our activities

are only beginning. We hope soon to issue a short book on the causes and characteristics of war as considered from a strictly medical point of view. Suggestions on possible research will be welcome as will any other proposals for furthering the objects of the Campaign.

Finally we express our hope that all members of our profession who are convinced of the urgency of action will place themselves in some relation with the existing Peace organisations such as the Peace Councils and the branches of the League of Nations Union.

On behalf of the Committee of the Medical Peace Campaign I am Sir yours faithfully

May 19th

JOHN A RYLE

THE METHYLATED SPIRITS (SCOTLAND) BILL

To the Editor of THE LANCET

SIR,—It must be assumed that the taste for that noisome fluid methylated spirit is sufficiently prevalent north of the Tweed to require an Act of Parliament to check its indulgence otherwise it is inconceivable that the Methylated Spirits (Scotland) Bill which is down for second reading in the House of Lords on June 1st should have passed through all its stages in the Commons. Is this crank legislation or is it not? The Bill as introduced into the House of Commons sought to control the sale in Scotland of methylated spirits by requiring that all purchasers of it should sign an entry in a book kept by the vendor for the special purpose of tracing the buyer who purchases the spirit in quantities less than four gallons. In other words a Scotoman might still buy 32 pints without disclosing his identity but if his requirements were for the modest quantity of say half a pint, whether to take the spots off his Sunday clothes or to boil water to add to a piece of lemon and something really worth while, he would unless he signed the book make the man who sold him the spirit guilty of an offence and liable on summary conviction to a fine not exceeding ten pounds or to imprisonment for a period not exceeding sixty days. For some reason or other surgical spirit was co-partnered with the other evil spirit in the course of the passage of the Bill through the Commons. Should this measure eventually receive the King's sanction all persons in Scotland who are ordered by their medical advisers to procure a supply of surgical spirit so that the patient in the house may be treated for bed-sores will have to go about the purchase of it in much the same way as they have to follow if they wish to purchase a deadly poison. This is not a Bill which should be hurried through Parliament. Its motive is good but the aim should be to stop the four gallon beano to introduce a very vulgar word rather than to place the slightest hindrance in the way of invalids suffering from bed-sores.

I am Sir yours faithfully

I C GOODALL

PRURITUS ANI

To the Editor of THE LANCET

SIR,—In your issue of May 8th Dr J T Ingram attacks my views on pruritus and in no uncertain manner and I will concede at once that I would have been wiser to leave out the word destructive in mentioning the possible effect of X rays on the vessels. His other thrusts are more easily parried.

He denies that itching is more apt to occur at body orifices than elsewhere but in my public gathering it is commoner to see people scratching

or rubbing the eyes, nares, corners of the mouth and ears than other part not excepting the healthy scalp. In children in whom social inhibition is not yet developed the same applies to the vulva and anus; and the first symptom of acute urethritis is frequently irritation at the meatus. This matter however was merely referred to in an introductory manner. I do not think the term prepruntio stage merits his sarcasm as it is merely another way of saying that the threshold to irritation is lowered and the variability of thresholds is an accepted physiological fact. I am well aware as I indicated in my article that the oedema is generally regarded as due to scratching and rubbing; but it does not follow that this view is correct. In fact I think it has been the greatest stumbling block to a proper conception of the disease. Dr Ingram states that oedema of the skin is readily provoked in the skin of the genitalia but in many cases of severe scabies in soldiers involving the scrotum and penis and exhibiting numerous scratch marks in that area I never saw any lesion even remotely resembling that of pruritus ani.

The constructive part of his letter is not quite clear to me but I may be allowed to refer to it. He says the indulgence in the pleasure of anal itching often creates the habit which is so difficult to break. Does he mean that the patient creates itching by auto suggestion and that the sensation arises in the sensorium? As scratching is used to relieve itching why does the patient scratch to get rid of a sensation which he likes? Why is pruritus ani a disease of middle age though habits are most easily acquired in childhood and youth? Dr Ingram complains that I dismiss the psychological side of the problem but psychology though a good servant is a bad master.

Major Porter in your last issue is I think unwise in the generalisation that pruritus ani is due to abnormal anal papillae. Papillae which are enlarged, inflamed or partially detached are often seen in the absence of pruritus, but they overlie veins passing down to the external haemorrhoidal area and these veins can hardly fail to be damaged when the papillae are cauterised. I am Sir yours faithfully

INSULIN SHOCK TREATMENT OF SCHIZOPHRENIA

To the Editor of THE LANCET

SIR,—Before subjecting patients suffering from schizophrenia to the train of events incidental to the depletion of glucose from the body fluids and tissues (referred to as hypoglycaemic shock) it is to be presumed that consideration will be given to the possibility that such a train of events may be due to colloidal precipitation. Having in view the cellular pathology of true schizophrenia the adoption of such a procedure would appear to entail especially serious risks. I am Sir yours faithfully

Stafford May 16th.

B H SHAW

To the Editor of THE LANCET

SIR,—I read Dr Fossell's letter in your last issue and having recently had the advantage of studying the latest modification of this treatment at Vienna and Minsingen I think it may serve a useful purpose to record the methods now adopted by these experienced workers in assessing the various depths of coma which we follow in our treatment at the hospital in Vienna and Minsingen the degrees of unconsciousness during hypoglycaemia are expressed as

light coma, deep coma, and very deep coma. The onset of "light coma" is noted as soon as the patient is unable to respond to external stimuli, such as calling his name or touching his body. He may be quiet or restless. His reflexes are present. The onset of "deep coma" is carefully noted and is characterised by loss of the corneal reflex. A sign I have seen frequently used is gentle blowing on the eyelids, in "deep coma" there is no finching. "Deep coma" is considered essential in treating excited and paranoid schizophrenics. It is never allowed to exceed one to one and a half hours. The patient is in a "very deep coma" when the pupils do not react to light. As long as the pulse and respirations are satisfactory this condition may be allowed to last for a short time, but the doctor keeps close to the patient and ready to interrupt the hypoglycæmia.

From personal experience in this hospital I find that frequent examinations of the conjunctival reflex delay the onset of deep coma and therefore I consider the absence of response to gentle blowing on the eyelids as a useful guide. When deep coma has lasted for several minutes a more thorough examination can be made with less likelihood of the patient returning into light coma (release of adrenaline).

Three Counties Hospital, Arlesey, Beds May 18th

A DISPUTED WILL

To the Editor of THE LANCET

SIR,—In THE LANCET of July 2nd, 1904, you were kind enough to publish an address I had recently delivered before the Hunterian Society on the subject of perforating typhoid ulcer. In it I drew attention to the fact that between the first symptoms of perforation and those indicative of the consequent fatal peritonitis, a remission of symptoms may occur to such an extent that the diagnosis of perforation may be abandoned, and I illustrated my remarks with details of cases. One of these is very pertinent to the case referred to in your last issue, for the patient, a man of 56, actually within a few hours of his death gave certain directions as to the disposition of his property. He was quite *compos mentis*, and I should have been prepared to testify that he had been so in any court of law had it been necessary, as I was present at the time.

I am, Sir, yours faithfully,

C W GOODALL

Hemingford Abbots Hunts May 16th

SPAIN OR INDIA ?

To the Editor of THE LANCET

SIR,—A letter in your issue of March 13th, under the heading *A Spanish Ambulance*, reminds me again of that peculiar characteristic of the British people which impels them to lavish their time, energy, money, and even their life blood for the relief of the foreigner in distress, whilst they will turn a completely blind eye on the needs of their fellow countrymen. Let a war break out, or some major national disaster occur in Spain or Abyssinia, or indeed in any country other than one belonging to the British Commonwealth, and at once appeals appear over distinguished names calling for money, doctors, nurses, and all the paraphernalia for equipping and dispatching medical units to the distressed area, and such appeals, apparently, meet a ready response.

Does it ever occur, I wonder, to those who promote and respond so generously to these appeals that there is surely room for their philanthropic efforts in our vast

Empire, and indeed even in our own small island? Do they realise, for example, that here, in India, there are vast areas where sickness, disease, and starvation are rife and where perhaps the only person to whom the people can look for the relief of their distress—if indeed there is anyone at all—is one underpaid and overworked missionary doctor?

I am not a missionary doctor, I hold no particular brief for missions, nor is this letter an appeal in aid of the medical missions, it is merely intended to indicate one channel into which I consider the charity of my fellow countrymen might more profitably be directed. However much one may feel for the unfortunate victims of the Spanish civil war, I think we should remember where charity ought to begin, and I personally would not give one farthing to aid a distressed Spaniard or Abyssinian so long as one fellow member of our Empire is in need of assistance and it is within my power to help him.

I am, Sir, yours faithfully,

Assam, India, April 20th

CIVANEO.

EXPLANATION AND APOLOGY

To the Editor of THE LANCET

SIR,—In the booklet recently issued by our firm in connexion with a block of flats in Dolphin square the name of Mr Hope Carlton, F.R.C.S., was mentioned as being a doctor in residence there and available in emergency. We regret to say that Mr Hope Carlton's name was inserted in this booklet without any authority from him, without his authority being sought, and without his knowledge, and we desire to express to him our sincere apology for the unauthorised use of his name and any inconvenience that he may have been caused thereby. Mr Hope Carlton is not practising at or from Dolphin square, which is his private residence, but he is continuing to carry on his practice as a consulting surgeon as before.

We are, Sir, yours faithfully,

RICHARD COSTAIN LTD

Dolphin square, Grosvenor road S W May 11th

THE FRUITS OF IDLENESS

To the Editor of THE LANCET

SIR,—Last week your Scottish correspondent again mentioned plans to shorten the students' summer vacation. Far be it from me to interfere with the traditional sport of overburdening the curriculum, nevertheless I venture to hand on the opinion of a group of young London consultants whom I lately heard discussing medical education. The question arose why the new Scottish graduate is a better doctor than his English contemporary. The answer was that his long summer holiday, his life in lodgings, and his habit of frequenting places of public refreshment bring the Scottish student into closer touch with real human beings and so promote an earlier maturity of judgment. The holiday also prevents staleness in teacher and taught.

Of course the argument breaks down at the source if the Scottish University authorities do not agree that their graduates are superior.

I am, Sir, yours faithfully,

Sussex May 18th

VULPIS

MEDICAL PRAYER UNION—On May 26th at 8 A.M., in the refectory of University College, Gower street, London W.C. this society is holding its annual missionary breakfast. The speaker will be Dr Clement Chesterman. Those who wish to attend should notify Dr Tom Javis, Livingstone College, Leyton, E 10.

OBITUARY

S. A. KINNIER WILSON M.D. D.Sc. Edin
FRCP Lond

THE death of Dr S. A. Kinrier Wilson removes from neurological medicine a great figure who gained early in life an international renown which was well deserved. If his name carried even greater weight abroad than at home this is not to imply that he lacked honours here but that his command of languages, his power of lucid exposition and his forceful personality carried his fame to places where the achievements of other British neurologists had not been accorded recognition. Perhaps his reputation abroad depended on the fact that neither in thought nor in teaching could he be considered as typical of the British school. Rather he kept up the tradition of the *Salpêtrière* in the days of Pierre Marie which had been one of his earliest inspirations and no doubt he owed much also to Hughlings Jackson of whom he was an enthusiastic disciple.

Samuel Alexander was the son of the Rev James Kinrier Wilson of Co Monaghan Ireland. He was born in New Jersey U.S.A. in 1878 and educated in Edinburgh at George Watson's College and the University of which he became M.A. in 1897. Bursaries and scholarships fell early to his hand before and after he began to study medicine. He qualified M.B. in 1902 and took his B.Sc. with first-class honours in physiology in 1903 after a period as house physician in the Royal Edinburgh Infirmary. In the same year he became a Carnegie research fellow and went to work in Paris with Pierre Marie. On his return to England in 1904 Kinrier Wilson was made house physician to the National Hospital, Queen's Square and he continued to serve this hospital in various capacities for the rest of his life becoming in turn resident medical officer, registrar and pathologist before his appointment to the honorary staff as assistant physician (1913) physician to outpatients (1921) and physician to inpatients (1925). These were years not only of preparation but of achievement. After taking the M.C.P. Lond. in 1907 Wilson produced what was acclaimed as an excellent translation of a French book by Meige and Fendel on ties and their treatment and in the next year published his first contribution to the study of apraxia. From 1909 to 1911 he held a B.M.A. research scholarship and in the latter year took his M.D. with a gold medal. In 1912 he contributed to *Brain* the description which was to become a classic of a familial nervous syndrome which has come to be known throughout the world as Wilson's disease. In the same year he was made a consultant physician to the Westminster

Hospital becoming dean of the medical school in 1914 when he was elected F.R.C.P. Lond. He resigned from the Westminster in 1919 on his appointment to King's College Hospital as junior neurologist and lecturer in neurology in the medical school. He became neurologist to the hospital in 1927 and senior neurologist in 1928 on the retirement of Dr W. Aldren Turner.

During the last 20 years the esteem in which Wilson was held for research, clinical acumen and for written and oral explanations of difficult neurological conceptions grew to such an extent that his leisure hours were few and were still further curtailed when in 1920 he became editor of the newly established *Journal of Neurology and Psychopathology*. Yet it was only within the last few years that he became only an occasional instead of a regular contributor of leading articles on neurological subjects to our columns and relinquished, with evident reluctance, routine reviewing duties.

Though Wilson's name is chiefly connected with certain aspects of disorders of motility and of multiple aphasia and apraxia, narcolepsy and hysteria, which he chose as subjects for monographs or official lectures—e.g. the Croonian lectures of the R.C.P. Lond. in 1923 and the Monroian lectures of the R.C.P. Edin. in 1930—we have good reason to know that his interests were as extensive as his knowledge was wide. At short notice he could and would supply wise comment, generous appreciation, reasoned criticism in words so nicely chosen that notices from his pen were a delight to read. His spoken words—as president

DR. KINNIER WILSON

of sections of the Royal Society of Medicine at the annual meetings of the British Medical Association at congresses or at public dinners—were no less apt in allusion and stimulating in content. This gift and the fact that he was no less agreeably fluent in German or French brought him more invitations to take a prominent part in professional gatherings than he could possibly accept. He was made an honorary member of the neurological societies of almost every European country and of the American Neurological Association and his personal contacts with workers in other countries were renewed and extended at his clinics at the National Hospital which were frequented by post-graduates from every land.

His interests in recent years are clearly reflected in a book entitled *Modern Views on Narcolepsy* published in 1928 which is much more than the collection of lecture and essays it looks to be. It starts with five chapters on the epilepsies followed by one on the narcolepsies in which Wilson examines the analogies between various narcoleptic symptoms with those

usually termed epileptic. An essay on the old (striato spinal) and the new (cortico spinal) motor systems forms an excellent introduction to the survey of the disorders of motility and of muscle tone, with special reference to the corpus striatum, which formed the subject of his Croonian lectures, here reprinted. The three final chapters are on pathological laughing and crying, on dysæsthesia and their neural correlates, and on the Argyll Robertson pupil. To all the subjects dealt with in this book and to many others he had made a personal contribution which never remained an isolated observation but was woven with infinite care into the complex pattern of current neurological ideas. It is a matter for deep regret that a man with such a power of clear logical thought on intricate neurological problems should not have been able to finish the text book of neurology on which he had been engaged for the last decade. The book is nearly complete, over three quarters of the text is ready. A further eighth has been written, but he wanted to rewrite it, and there remains an eighth which existed only in the form of rough notes. His colleagues and disciples had expected this work to become a standard international text book as important to modern neurologists as was "Gowers" in the late 'nineties, and it is greatly to be hoped that they will be able to arrange for its completion. Wilson's knowledge of his subject was encyclopædic, he read widely and possessed a remarkable memory in which the enormous clinical material that passed through his hands during his many years as out-patient physician at the National Hospital, and as consultant neurologist to the Metropolitan Asylums Board, and, later, the London County Council was safely stored. He was a splendid teacher, with a flair for the unusual phrase that remains in the memory when most of the rest is forgotten, and a delightful informal talker. His lectures and demonstrations were always crowded because there was always something fresh, if not in the case or the subject at least in the manner of presentation. An assistant medical officer at the Fountain Hospital writes "Dr Kinnier Wilson's visits to this hospital for mentally defective children were a stimulus and an inspiration. His avid curiosity and his provocative speculations set us hunting for material between his visits and gave a new impulse to routine physical examinations. If we had some half formulated theory to put forward he was always eager to discuss it, drawing on his own profound experience to check and encourage our reasoning. He was a teacher in the Hippocratic tradition."

The personal side of "Sam" Wilson is not easy to convey to those who did not know him. Strangers were apt to take for hauteur what was only abstraction. He had no facile social grace, nor could the barrier round him be scaled once and for all. The approach remained difficult for all but a band of close friends who knew that he welcomed their advances even if he was unable to help them to reach and retain intimacy, and the depth of his affection was apparent when his friends were in any trouble. His interests outside his library were golf—as a left handed player—his garden at Thorpeness, and his family. He married Annie Louisa, daughter of Dr Alexander Bruce, who survives him with two sons and a daughter.

Dr Macdonald Critchley writes "A mere recital of international honours and academic distinctions does not adequately describe the place occupied in British neurology by the late Dr Kinnier Wilson. Although trained on a firm foundation of physiology,

anatomy, and pathology, Wilson was at heart essentially a clinician with a philosophical and reflective outlook. In this respect he was inspired by the friendship and precepts of his revered Hughlings Jackson, with whom as a very young man he became closely acquainted. Besides his outstanding abilities Wilson was gifted with an exceptional memory and a sure command of language. He wrote easily and clearly in a style which was individual. His writings, which covered a large range of neurological subjects, had the uncanny faculty of throwing light from an unusual angle upon the problem concerned. In this way his papers were particularly inspiring, always refreshing, and sometimes provocative. Wilson's approach to a problem invariably went beyond a simple recording of observed data—a style of publication which he dubbed as merely 'descriptive'—and he would always inquire in a reflective and thoughtful manner into the *modus operandi* of clinical phenomena. In this way all his writings were rich in speculative and stimulating matter. The monograph, published while yet a registrar at the National Hospital, which won him international fame was his well known thesis on 'progressive lenticular degeneration,' a malady which bears his name. This particular work may be regarded as the impetus to the world wide interest in the normal and morbid physiology of the basal ganglia. Wilson felt that much of the subsequent work went considerably too far into the realms of the imagination, and his Croonian lectures on 'Disorders of Motility' were written as a protest against this striatal jerry building.

"Wilson will especially be remembered by his pupils as a lecturer. He was probably one of the finest modern medical speakers, eloquent and witty in his choice of language, with a supreme ability for arousing the interest and attention of his listeners, and for stage managing his material. His clinical demonstrations at the National Hospital were attended by throngs of students from all over the world. His numerous pupils and assistants will be the poorer without his genial and stimulating inspiration. No one was more gifted than he in the ability to illuminate difficult neurological problems and his valuable time was always at the disposal of his juniors. In these days of mediocrity, Wilson stood out as a 'big man'—one who will be remembered for his bonhomie, brilliance, and kindness of heart. His keen sense of humour—rare in one so witty—will be sadly missed wherever neurologists foregather."

GEORGE EVERARD DODSON, M.R.C.S. Eng., D.T.M. and H.

WE regret to announce the death of Dr G. E. Dodson from typhus fever on May 9th at Kerman, Iran (Persia), where he had charge of the Church Missionary Society's Hospital. Born in 1872 at Higher Crumpsall, Manchester, he was educated at Giggleswick grammar school and St Bartholomew's Hospital. He qualified in 1897 and became extern midwifery assistant and assistant in the orthopaedic department at Bart's, gaining experience which he turned to good use later. After further hospital work at Norwich, Bath, Nottingham, and elsewhere, he was accepted by the Church Missionary Society for service in Persia, and with his wife, Miss E. L. Wells, a trained nurse, he left England in 1904. "During his 34 years of service under the C.M.S.," writes a colleague, "Dr Dodson did a work for Iran which will never be forgotten. He was a gifted surgeon, and laid the foundation of a social service

and welfare activities—especially at Kerman—which has been of inestimable value. Two outstanding features of his professional practice were his orthopedic work amongst the crippled carpet weavers and the skilful obstetrical and gynecological work which has saved the lives of large numbers of dwarfed cripple-mothers in that industry. No less important were the preventive and welfare services which he instituted, and which led to legislation that has gone far towards revolutionising the conditions of the

carpet industry in the cities of Iran. As a missionary he was honoured for his high sense of duty, his lovable personality and his unsparring self-sacrifice. He died, as he would have wished, among the people whom he had served and for whom he has given his life.

During the late war Dr Dodson held a captain's commission in the Royal Army Medical Corps and was surgical specialist at the Colaba War Hospital Bombay.

PUBLIC HEALTH

The Smoke of Britain

ON the whole the pollution of the atmosphere in this country has been reduced during the last twenty years. This is the conclusion reached in a report by the Department of Scientific and Industrial Research¹ which summarises measurements by 72 municipal and other bodies. Some of the figures show a small increase during the last two years—presumably because of increased industrial activity—but the outstanding feature of the curves is the large decrease in pollution at many places before the industrial depression of 1930-33 started.

The records for London show improvement between 1916 and 1922 but from then until 1936 there was little change in the total solids, an increase in the deposit of sulphates and if anything an increase in the deposit of tar. On the other hand it is considered encouraging that in the winters of 1931-35 central London enjoyed 52 per cent of the sunshine obtainable at Kew (which naturally shows a small deficiency compared with the more southerly districts) compared with 20 per cent, in 1881-85. In Edinburgh (Princes-street) the pollution is getting rather worse. Glasgow records a steady improvement from 1916 to 1923 but from then onwards there has been little change. At St Helens the total solids deposited has fallen from 612 tons per square mile in 1917-18 to 447 tons in 1935-36 but the improvement has not been continuous. The total deposit at Wakefield fell from 613 tons per square mile in 1924 to 227 tons in 1935—that is, by almost two thirds in ten years. Sulphates fell from 136 tons in 1924 to 22 tons in 1930 rising somewhat later to 24 tons in 1935. Tar decreased from 8 tons in 1924 to 6 tons in 1936.

An attempt has been made to trace the trend of affairs for suspended impurities which produce smoke haze as well as matter deposited from the air. In this respect the London stations do not all tell exactly the same story but there is again a general indication of improvement. In four out of five of the observing stations however the results for 1935-36 indicate a higher degree of pollution than 1934-35. In Glasgow there has been almost no change. The results for Cardiff which indicate a lower level of pollution than most of the others have a slight tendency to get worse.

The figures for tar in 1936 indicate an increase. One of the worst stations for tar deposits was Golden Lane, London, where the tar deposit in the gutter was at the rate of 10.41 tons per square mile an increase of 213 per cent on the general average for the last five years. The deposit of total solids which the report states may be regarded as a summary of all the others indicates that 1936 compares unfavourably as a whole with 1931-35. The greatest increase was found in London (Finsbury Park) with an annual

deposit of total solids at the rate of 40.12 ton or 178 per cent of the general average. Finsbury Park also showed a large increase in the deposit of sulphates with a figure of 311 per cent of the general average. The next greatest deposit of sulphates was at Halifax (Westview Park) with 242 per cent.

Records of the amount of sulphur gases in the atmosphere which are believed to have a considerable effect on the deterioration of building stone and possibly (in high concentrations) on health were made at eleven stations. The sulphur appears to be mainly a winter problem. London shows the highest average pollution of any of the cities and a very obvious seasonal variation pointing again to the domestic fires as a contributory cause. Although doubtless the electric generating stations also burn more fuel in winter than in summer. Of the London stations Westminster Bridge and Westminster City Hall show the most sulphur pollution. Last year the highest concentration was found in London but this year the highest figure found was in Salford during December. Sulphur pollution at Greenwich appears to be about one third of that in the vicinity of Westminster. It seems that Greenwich although suffering from smoke haze as much as London does not suffer equally from sulphur pollution and this suggests that in London there are sources of sulphur which are not serious sources of smoke. This again points to industrial furnaces which have no provision for absorption of sulphur.

Publicity for Venereal Disease

The Minister of Health has sent a circular asking counties and county boroughs to tell him what steps they are taking to disseminate information about venereal diseases. There is evidence the circular says that the public in many parts of the country are still insufficiently informed about the importance of these infections and the necessity for early and skilled treatment. The reports from treatment centres suggest that in many areas only a small proportion of women with the venereal diseases—especially with gonorrhoea—take advantage of the facilities offered. Moreover a substantial proportion cease attendance while they are still potentially infectious. It is of the utmost importance in the Minister's opinion that patients should appreciate the necessity—in their own interest and in that of the community—for completing their treatment. To this end he commends a policy of continuous education and enlightenment. So as to be able to judge how this policy may be developed and rendered more effective he is asking, for full particulars of the arrangements at present made. One of the questions asked is whether a contribution is made to the British Social Hygiene Council and if so what work is done by the Council in the area.

¹Investigation of Atmospheric Pollution. London. H.M. Stationery Office. 1937. 1 p. 1. 6

"Flying Clinics" in Somerset

In order to deal with the medical supervision of maternity and child welfare work in rural areas, Dr W G Savage, the medical officer of health for Somerset, has instituted a system of "flying clinics" which he considers to be far superior to a system of small fixed welfare centres covering the county. The clinics are held when and where occasion arises, often at the request of the infant visitor, and may take place at a nurse's house or at a room taken for the purpose, or visits may be undertaken to several scattered houses in a district. The visiting of children at their homes makes it possible to include those who might well be unable or unwilling to bring their children to a centre. Where the clinics prove welcome and popular they are repeated at short intervals and if the need in any such area, later diminishes, the clinic can easily be discontinued and the work done elsewhere. In his annual report Dr Savage states that the four medical officers held 311 of such sessions during 1935 and attendances totalled 3525, including 115 antenatal and 126 post-natal mothers. It would seem that such clinics might be of very real value to practitioners in outlying districts by providing opportunities for consultation where circumstances would otherwise make a second opinion very difficult to obtain.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED
MAY 8TH, 1937

Notifications—The following cases of infectious disease were notified during the week. Small-pox, 0, scarlet fever, 1882, diphtheria, 985, enteric fever, 36, pneumonia (primary or influenzal), 949, puerperal fever, 35, puerperal pyrexia, 99, cerebro spinal fever, 33, acute poliomyelitis, 1, acute polio encephalitis, 1, encephalitis lethargica, 0, dysentery, 20, ophthalmia neonatorum, 101. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 14th was 2069 which included. Scarlet fever, 797, diphtheria 852, measles, 77, whooping-cough, 481, puerperal fever 18 mothers (plus 11 babies), encephalitis lethargica 283, poliomyelitis 0. At St Margaret's Hospital there were 24 babies (plus 12 mothers) with ophthalmia neonatorum.

Deaths—In 123 great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 19 (0) from measles, 4 (3) from scarlet fever, 12 (1) from whooping-cough, 35 (5) from diphtheria, 64 (23) from diarrhoea and enteritis under two years, and 31 (7) from influenza. The figures in parentheses are those for London itself.

Five deaths from diarrhoea and enteritis under two years were reported from Liverpool and 3 each from Nottingham and Bradford. Salford, Sunderland and Liverpool each had 3 fatal cases of diphtheria. There were 3 deaths from measles at Birmingham and 3 from whooping-cough at Liverpool.

The number of stillbirths notified during the week was 291 (corresponding to a rate of 41 per 1000 total births), including 38 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg Rear Admiral P T Nicholls, CB, KHP, to be President for service inside Admiralty Medical Department.

Surg Capt R F P Cory to President for course. Surg Capt J H Burdett, professor of medicine at Haslar Hospital to R N Hospital, Chatham.

Surg Cmdrs M B Devane and A W Gunn, MVO, to Victory for R N B. J A Cusack to Pembroke for R N B, and A W McRorie to President for course. Surg Lt Cdr F Dolan to Drake for R N B.

Surg Lts G H C R Critson to Drake for R N Hospital, Plymouth, D B Jack to Pembroke for R N B. R V Kirkwood to Pembroke for R N B and to Pegasus, R M Bremner to Hastings, D D Steele Perkins to Pembroke for R N B and to Ganges, and I C Macdonald to Cardiff and to R N B, Chatham.

ROYAL NAVAL VOLUNTEER RESERVE

Surg Sub Lt C P Nicholas promoted to Surg Lt.

ARMY MEDICAL SERVICES

The War Office announces the following appointments. Colonel R W D Leslie, OBE, LRCP, Officer Commanding, The Queen Alexandra Military Hospital, Millbank, SW 1, has been selected for promotion to the rank of Major General from August 10th, 1937 and to be Deputy Director of Medical Services, Northern Command, York, in succession to Major General G G Tabuteau DSO, who is taking up the appointment of Director of Medical Services in India.

Colonel A D Fraser, DSO, MC, MB, who commands the Royal Army Medical Corps Depot and Training Establishment at Aldershot, has been selected for promotion to the rank of Major General from Oct 13th, 1937, and to be a Deputy Director of Medical Services in India, in succession to Major General D S Skelton, CB DSO, honorary physician to the King, who will vacate the appointment on completion of four years' service as a Major General.

ROYAL ARMY MEDICAL CORPS

Maj J R S Mackay retires on ret pay.

Short Service Commissions. Lt P Coleman to be Capt. The following candidates have been selected for short service commissions as Lts on probation. F Livesey (Manchester Univ), C E McCloghry (Queen's Univ, Belfast), C McNeil (Cambridge Univ and St Bartholomew's Hosp), G G Sherriff (Edinburgh Univ), G M Curtis and E Garoh (Guy's Hosp), J B Bunting (Cambridge Univ and St Thomas's Hosp), R B Robertson (St Andrew's Univ), A T M Glen (Westminster Hosp), K F Stephens (London Univ and St Bartholomew's Hosp), G M Robertshaw and O W W Clarke (The London Hosp), R L Townsend (Cambridge Univ and University Coll Hosp), F J S Baker and J B Dancer (St Bartholomew's Hosp), O Jordan (St Mary's Hosp) and N Bickford (Cambridge Univ and Middlesex Hosp).

The following Lts (on prob) are sec'd, under the prov of Art 213, Royal Warrant for Pay. C McNeil and F J S Baker.

REGULAR ARMY RESERVE OF OFFICERS

Lt Col G H Stevenson DSO, having attained the age limit of liability to recall, ceases to belong to the Res of Off.

TERRITORIAL ARMY

F C Angor to be Lt. P Howe (late Offr Cadet, Liverpool Univ Contgt, Sen Div, OTC), to be Lt, E H P Smith (late Cadet Serjt, Epsom Coll Contgt, Jun Div, OTC) to be Lt, K G S Bavidge (late Offr Cadet, Durham Univ Contgt (Med Unit), Sen Div, OTC), to be Lt and A G McCallum (late Offr Cadet Glasgow Academy Contgt, Jun Div, OTC), to be Lt.

The Efficiency Decoration has been conferred under the terms of the Royal Warrant dated Sept 23rd, 1930, on Maj Alfred Pam.

TERRITORIAL ARMY RESERVE OF OFFICERS

Capt D M Mackenzie from Active List to be Capt.

ROYAL AIR FORCE

Flight Lts promoted to the rank of Squadron Leader: R E Alderson and J Kemp.

INDIAN MEDICAL SERVICE

Lts (on prob) to be Capts (on prob)—S C Colbeck, J H Bowie, W S Empey, OBE, A G Miller, E H Wallace and J F Thomson.

Lts (on prob)—G R Kerr, B J Doran, and J D Munro are res'd to the estab.

To be Lts (on prob) S Shone, J H Walters, C F Mayo Smith, W C Templeton, G W Palmer, G F J.

(Continued at foot of opposite page)

King's College Hospital

The Listerian Society of this hospital will meet on Wednesday, May 26th, at 8.15 p.m., when Dr Edward Mapother will deliver a presidential address. His subject will be the psychiatry that is coming.

Medical Caricatures and Cartoons

The Staatliche Medico Historische Sammlung in Berlin intends to hold next autumn an exhibition of caricatures and cartoons dealing with medicine. It will comprise both caricatures of individual members of the profession and cartoons concerned with various methods of treatment and diagnosis, and it will cover the past as well as the present. The organisers feel sure that many sketches will be available in various publications of medical and students' societies, while periodicals such as *Punch* and the *New Yorker* should also furnish plenty of material. Anyone in possession of such material or knowing where it may be found is asked to communicate with the Staatliche Medico Historische Sammlung at the Kaiserin Friedrich Haus, Robert Koch Platz 7, Berlin, NW 7.

British Postgraduate Medical School

An intensive course, intended primarily for practitioners, will be held at this school from May 31st to June 12th (10.30 to 4.30 daily). Among those giving lectures and demonstrations will be Prof Thomas Beattie, Prof G. Grey Turner, Dr E. R. Cullinan, Mr R. J. McNeill Love, Dr R. T. Brain, Dr Evan Bedford, Dr J. R. Rees, Mr C. I. Naunton Morgan, Dr T. C. Hunt, Dr James Maxwell, Dr Janet Vaughan, Dr J. Chassar Moir, Dr W. Gunn, Mr St. J. D. Buxton, and Dr H. Gardiner Hill. Sessions will also be held at the Central London Throat, Nose, and Ear Hospital, the Red Cross Clinic for Rheumatism, the Royal London Ophthalmic Hospital, the Hospital for Sick Children, Great Ormond Street, and the National Hospital, Queen Square. Early application for membership of this course is recommended, and further information may be had from the dean of the school, Ducane Road, London, W 12. Similar courses lasting a fortnight will begin on June 28th, Sept 20th, Oct 18th, and Nov 15th.

Beginning on May 25th, at 4.30 p.m. on Tuesdays Dr Donald Hunter will give six lectures on occupational diseases. Prof M. Greenwood, F.R.S., will lecture on experimental epidemiology on June 2nd, 9th, and 16th at the same hour.

Medical Sickness, Annuity and Life Assurance Society

At the annual meeting of this society held in London on May 10th, Dr F. C. Martley, the chairman of directors, reported a very satisfactory result of the actuary's valuation for the 44 years ending last December. The total surplus on sickness and life assurance funds amounted to £225,639, of which it was proposed to distribute £153,000 as bonus and to carry forward the remainder. The bonus was to be increased from 12s to 15s per annum on the main class of sickness policies for each guinea per week insured, and from 23s to 25s per annum on the life assurance side for each £100 insured, together with a bonus on all combined policies at the same rates as if separate policies had been effected for the two benefits. During the year under review the new sums assured under life assurance amounted to close upon half a million, the total premium income in this department was now £111,856. A large proportion of the total premiums was in respect of the deferred annuities under the scheme which the society helped to operate for members of the British Medical Association and for insurance practitioners. The society's family provision policy was also proving very popular. Its chief advantage was that at the age of sixty the premiums paid did not disappear but a guaranteed sum was payable. On the sickness fund the new annual premiums totalled to £10,702 which constituted a record; the premium income on this fund amounted to £108,637. Not only were the society's rates lower than were obtainable elsewhere, but it paid a bonus at the normal termination of each contract. The expenses of management were just over 9 per cent of the premium income and represented a reduction on previous years.

Dr Martley concluded with a word of appreciation of the staff, in particular Mr Bertram Sutton, manager and secretary, Mr E. A. J. Heath, and Mr C. L. Venus.

The meeting unanimously adopted the report of the directors and re-elected those who retired by rotation (Dr W. Knowles Sibley and Mr R. J. McNeill Love). On the proposition of Mr Cecil Wakeley, seconded by Dr Fairfield Thomas, the meeting also unanimously agreed to an increase in the remuneration of the directors. Sir William Willcox moved a vote of thanks to the chairman and this was seconded by Dr G. de Bee Turtle.

Inter-Hospitals Sports

The sixty-sixth annual inter hospitals sports will be held on Wednesday, May 26th, at 2.30 p.m., at the Duke of York's Headquarters, Chelsea.

Greater London Provident Scheme for District Nursing

For nearly 70 years district nursing has been provided in London largely as a charity, but as the work grew it has been found necessary to ask for payment, by the visit, from those who could afford it. This sometimes caused a financial strain in times of illness. To avoid this under the new scheme launched last month (*Lancet*, April 24th, p. 1020) payment will be made in the form of small weekly contributions. Any person who works in a place where five or more people are willing to join the scheme, and whose earnings do not exceed £8 per week can call upon the services of a district nurse for himself and his dependents for a weekly contribution of 1d. If all his fellow workers take advantage of the scheme, the subscription for each employee will be only 1d per week. Anyone whose income exceeds £8 per week but does not exceed £400 a year may join the scheme for a weekly contribution of 1½d. Further information may be had from the offices of the scheme, 1, Sloane Street, London, S.W. 1.

Maternity and Child Welfare Conference

The seventh English speaking conference on maternity and child welfare will be held at B.M.A. House, Tavistock Square, London, W.C., on June 1st, 2nd and 3rd. The following is a list of speakers and subjects: Dr Mary Blacklock, Dr Mabel Brodie, and Mrs Randal Hosking (the promotion of maternity and child welfare in backward and in rural areas); Mr R. J. Howard Roberts and Miss Eleanor Harwarden (progressive legislation in connexion with maternity and child welfare); Dr Eric Pritchard, Dr Ursula Cox, and Mrs Charlesworth (the education of parents in the care of their children); Dr Robert McCance and Dr Reginald Jewsbury (nutritional problems in relation to mother and child); Dr Margaret Lowenfeld and Dr J. A. Hadfield (the future of preventive psychology in relation of parent and child); Dr B. E. Schlesinger and Mr E. S. Evans (preventive work for cripples and invalid children). Visits will also be paid during the conference to various institutions in and near London, and on May 30th and 31st a short post graduate course has been arranged by the maternity and child welfare group of the Society of Medical Officers of Health. A child welfare exhibition will be held in connexion with the congress at Woburn House (exactly opposite B.M.A. House). Further information may be obtained from the hon. secretary, Carnegie House, 117, Piccadilly, W. 1.

Appointments

ANSON C. E. H. M.B. Lond. has been appointed Medical Superintendent of the Royal National Sanatorium, Bournemouth.
 ASCROFT P. B. M.S. Lond. F.R.C.S. Eng. Assistant Surgeon to the Middlesex Hospital.
 BARNIE C. R. M.D. M.R.O.P. Lond. D.P.M. First Assistant Medical Officer at West Park Hospital, L.C.C.
 *BULLOUGH A. S. M.B. Manch. Resident Assistant Medical Officer (Grade II) at Withington Hospital, Manchester.
 *CURRIE F. R. M.B. Leeds, Assistant Pathologist at White chapel L.C.C. Clinic.
 DALZIEL A. C. M.D. Lond. D.P.M. Second Assistant Medical Officer at Bexley Hospital, L.C.C.
 GILMOUR J. M.B., F.R.C.S. Eng. Hon. Surgeon to the Royal Victoria Infirmary, Newcastle upon Tyne.
 MCGUCKIN FRANK M.D. Durh. F.R.C.S. Edin. Consulting Surgeon for Throat, Nose and Ear Cases at the Newcastle-upon Tyne General Hospital.

NOTES, COMMENTS, AND ABSTRACTS

THE RED CROSS RHEUMATISM CLINIC

THE annual report of the British Red Cross Society's Clinic for Rheumatism shows that the work is steadily increasing and that the attendances in the general department were 5812 more than in any previous year. While this increase is a tribute to the value of the work carried out at the clinic the figures also imply that its accommodation is being unduly strained, and the burden imposed on the staff is heavy. If long periods of delay before patients urgently needing treatment can be accepted are to be avoided, it is essential that the premises should be enlarged. We understand that schemes to this end are already under consideration and it is to be hoped that the authorities will soon be in a position to carry them out. More funds are urgently needed. The results of treatment according to the records appear to be very satisfactory, 80.3 per cent patients were discharged free from symptoms and a further 29 per cent were definitely improved. The medical board modestly point out that these figures should be accepted with some reserve. The clinic is not only a centre for treating professional and industrial workers, research is being actively pursued on the valuable clinical material available under the direction of a special committee formed last year for the study and investigation of rheumatism. The lack of in-patient accommodation hampers research and that also should be made available when funds permit.

INSTITUTIONAL TREATMENT OF EPILEPSY IN SCANDINAVIA

THE alertness of the Scandinavian countries about each other's virtues and vices is partly responsible for the high level of their culture. For one country to lag behind in some good work is to invite disparaging comparisons in the other countries, and at the present time, Denmark, Sweden, and Finland are being held up as examples to Norway as regards the institutional treatment of epilepsy. Denmark comes first in this comparison with 2 beds for epileptics for every 10,000 inhabitants, Finland comes next with 1 bed, and Sweden comes third with 0.9 bed, whereas the corresponding figure for Norway is only 0.25. A census of epileptics conducted in Norway in 1929 by medical officers of health showed that there must be about 1900 epileptics, of whom more than 400 require institutional treatment. It is more than probable that this census failed to include many slight cases of epilepsy, and the figures quoted are assuredly under-estimates. For the more than 400 epileptics requiring institutional treatment there are at present only 68 beds in Norway, and this glaring discrepancy between supply and demand has led to the appointment by the Government of a committee charged with the task of estimating the country's requirements for beds for epileptics, and with drafting legislation for their care. This committee's studies have been extended to England and Germany as well as to the other Scandinavian countries.

The experiences of Denmark have proved most instructive. She is the only Scandinavian country in which a hospital for adult epileptics has been created. It is "Filadelfia" with accommodation for 445 epileptics over the age of fifteen. Of its seven medical officers, two are specialists in neurology and mental disease. Epileptics who are imbecile from birth are drafted as much as possible into institutions for the mentally defective, and the inmates of Filadelfia are encouraged to find recreation in work such as carpentering, shoe making, tailoring, book-binding, &c. In addition to this hospital there are four smaller institutions: the accommodation of all five being 680 beds. In Sweden there are eight institutions for epileptics and "Stor Sköndal," with 212 beds serves as the central hospital in the neighbourhood of Stockholm. Altogether there are some

700 beds for epileptics in Sweden, and it is the ambition of Prof. Petréén to centralise the institutional treatment of epilepsys as much as possible, and to attach to a large epileptic hospital a department for mentally defective and insane epileptics. In Finland, with some 300 beds for epileptics, there is the same tendency as in Denmark and Sweden to favour a large central institution. It is held that the larger the institution the more skilful will be the treatment. The institution which is too small to employ a resident medical officer is bound to give comparatively inadequate service.

DANGERS OF ARTERIOGRAPHY

SINCE arteriography is sometimes recommended as innocuous E. Verschuyt has thought it well to bring forward a number of cases in which it gave rise to complications (*Ned. Tydschr. Geneesk.* 1937, 81, 1007). Two of these were in his own practice.

(1) A man, aged 70 was admitted to hospital with a history of sudden pain and numbness of the right leg. The entire limb was blanched and could not be moved actively: it was tender and felt cold. No pulsation could be detected in the dorsalis pedis, popliteal or femoral arteries. The vessels did not feel hard or thickened. A systolic murmur was heard over the heart. The diagnosis was thought to lie between acute spasm and embolic obstruction of the femoral artery, and arteriography was decided upon. The abdominal aorta was punctured, 20 c.cm. of 35 per cent Perabrodil was rapidly injected, and an X-ray photograph was taken. This showed that the solution had not passed on the right side beyond the upper part of the common iliac artery. Immediately afterwards, however, the pain ceased, the limb resumed its normal colour and temperature, and could be moved actively. A diagnosis of spasm was made. A few days later the patient suddenly died and at autopsy a rupture of the ascending aorta was found. Verschuyt attributes this to damage caused by the injected fluid, for apart from a few small plaques of atheroma the aorta appeared healthy.

(2) A woman aged 28, complained of pain in the right forearm, with cyanosis and swelling. Other abnormal signs were absent and there was no history of trauma. The diagnosis of angioneurosis was made and arteriography was performed, 20 c.cm. of perabrodil being injected into the subclavian artery. The patient was immediately seized with a typical epileptic fit lasting about two minutes and followed by severe headache. She recovered completely in about 30 hours, and the arteriogram revealed no abnormality.

Verschuyt concludes that arteriography is by no means devoid of danger and that it should not be lightly employed.

PULMONARY EMBOLISM AFTER INJECTIONS INTO VARICOSE VEINS

Dr. Anders Westerborn of Varberg, Sweden, has recently published¹ a study which should do much to dispel fears about fatal pulmonary embolism more or less directly due to the thrombosis induced by injections of various substances into varicose veins. His investigations were in part prompted by a lurking suspicion that such fatalities do not always get into the medical press, the urge to publish successes being notably greater than any willingness to admit disasters. However instructive they may be. In 1929 H. O. McPheeters and C. O. Rice (*J. Amer. med. Ass.* 1928, 91, 1000) found in reports by various authors a mortality of only 0.0075 per cent, and a similar review by K. Ketteln in 1931 (*Zbl. Chir.* 1931, 58, 1498) raised the figure to 0.017 per cent. To avoid the sources of error inherent in such compilations, Westerborn addressed inquiries to all the 93 hospitals in Sweden. Information was obtained from 80, and he was able to calculate that in the period 1927-34 some 30,000 patients with varicose veins must have

¹ *Acta chir. scand.* 1937, 79, Fasc. IV, p. 321.

been treated in the 93 hospitals by the injection of thrombogenic solutions. The 11 deaths from pulmonary embolism and the 6 severe cases with recovery in this material represented what may be considered as a comparatively accurate picture of the embolism risk. The mortality was 0.036 per cent—considerably higher than that obtained from other published work yet many times lower than that for more radical operations on varicose veins. In the five-year period 1931-2, 6001 operations not yet ousted by the injection treatment were performed on varicose veins in 82 Swedish hospitals and 18 patients died of pulmonary embolism—a mortality of 0.26 per cent the corresponding figure obtained by McPheeters and Rice being 0.1 per cent (36 deaths from embolism among 6071 cases). Though this comparison with operative treatment is favourable to the injection treatment it is not quite fair to the latter which is still in its youth and many of whose fatalities may be due to avoidable mistakes. Westerborn traces a goodly proportion of the embolism fatalities to infections, local or general and to the stagnation of circulation promoted by confinement to bed after an injection. He regards the bedridden state as a definite contra indication and he is in favour of keeping a patient out of bed as much as possible just after injections. His comparison of the embolism rates for the different chemicals used shows that there is little to choose between them so long as they are not introduced as isotonic solutions. It is curious how different countries prefer different chemicals. In the past quinine urethane has been the most popular in Sweden, America and England whereas Germany and Central Europe have preferred solutions of sugar and sodium chloride. Now it seems that quinine-urethane is being displaced by sodium morrhuate which has the advantage of not provoking necrosis of the tissues when a perivascular injection is given by mistake.

CECIL HOUSES

FOUNDED ten years ago by Mrs Cecil Chesterton the public lodging houses for women known as Cecil Houses fill what was a very serious gap in the provision for London's homeless. With the reopening this year of the house in Devonshire-street, Theobalds-road there will be five houses in the London area each providing clean beds, hot baths and facilities for washing clothes for from fifty to sixty women at a cost of a shilling a night for each woman. There is also accommodation for babies at the houses, which are non-sectarian; any homeless woman is admitted and no questions are asked. Once the initial capital expenditure of some £7000 is found a house becomes entirely self-supporting although subscriptions are much needed for replenishment and the extension of activities. In addition to their primary object of providing lodging the staff are able to find employment for a number of those who are in need of it and do much to help the women to regain their self-respect by the distribution of gifts of clothing and boots and shoes.

NEW PREPARATIONS

THE Crookes Laboratory (British Colloids Ltd.) of Park Royal, London, W.10, now issues their Colloidal Brand PRO-PRO-MANDELAT in a box containing all that the patient wants for carrying out six days' treatment. The ammonium phosphate is white; the mandelic acid is coloured pink, and containers showing the exact doses are provided together with a book of test papers for determining the approximate pH of the urine.

THE PROPHYL ATOMISER is used as a spray for throat or nose. Its chief advantages are that it has a screen cap which closes it when travelling; that it can be conveniently used with one hand; and that it provides a fine vapour. The manufacturers (Prophyl Co. Ltd., 7 Prince-street, S.W.1) make an oily antiseptic fluid (Prophyl No. 1) for use as a spray in the prevention or treatment of colds and influenza. The formula is given as follows: 1.000

0.025; phenol 0.2; iodo 0.02; sodium ricinolate 0.1; menthol 0.02; liquid paraffin to 100.

A booklet on the Technique of Parenteral Calcium Medication with special reference to CALCIUM-SANDOZ is published by J. Flint, Sandoz Products, 134 Wigmore-street, London W.1. It points out that the ease and safety of giving calcium in adequate doses by injection has extended the applications and improved the results, of this form of treatment. With excellent illustrations it describes exactly how Calcium-Sandoz is best injected including an account of intrapleural administration and of intranasal submucous injection as recommended in THE LANCET by Prof Bárány shortly before his death. The manufacturers claim that a satisfactory solution of calcium gluconate is by no means easily prepared and state that Calcium Sandoz, the first to be introduced is always tested clinically for each batch before general issue. The ampoules now contain calcium gluconoglucoactogluconate which has advantages over the ordinary gluconate.

Particulars of the many bismuth products of PHARMACEUTICAL SPECIALITIES (May and Baker) Ltd. Dagenham are given in a small book on BISMUTH THERAPY in which they summarise the history of bismuth as a remedy, its mode of action, its clinical application and the way in which it is used. For the intravenous injection of bismuth it is recommended that the needle when introduced should have an empty syringe attached to it. When by withdrawing blood it has been ascertained that the needle is in the vein a second syringe filled with the drug is substituted for the first. Deep subcutaneous injection may be preferred; but in any case deep and firm massage is advisable to spread the bismuth after its administration. Precautions against stomatitis and other possible complications are mentioned.

A NEW REMEDY FOR HÆMORRHOIDS

IN a preliminary note on the use of an extract of *Microseris dubius* in the treatment of hæmorrhoids H. E. Mercante and J. F. H. Piazza describe their results in 12 cases (*Rei und anner Endocrin* 1937, 20, 61). The method adopted was continuous application on cotton wool of a 5 per cent oil solution of an extract of the whole worm. The result it is said in all 12 cases was cessation of pain, pruritus, and other subjective symptoms and bleeding too ceased almost at once. In recent cases a course of treatment lasting 15-20 days was followed by clinical cure with no relapses during a period of observation of nine months. The solution was successfully employed also in a case of varicose ulceration of four years' duration and the ulcers were fully healed after 11 days of treatment. Clinical and laboratory investigations of the new remedy are being continued.

CLINICAL AND LABORATORY PHOTOGRAPHY.—Messrs Kodak Ltd. have constructed what they call a clinical camera outfit—an advanced photographic unit intended to have a precise comparison with that of other instruments that assist workers are accustomed to handle. It is meant to satisfy the exacting demands of the medical worker but also to find many applications outside medical work. Particulars may be had from the makers at Kodak House, Kingsway, London W.C.2.

Vacancies

THE BIPP METHOD OF TREATMENT OF ACUTE OSTEITIS*

By JAMES H. SAINT MILDURD, F.R.C.S. Eng.
F.A.C.S.

CONSULTING SURGEON TO THE THOMAS ROBERT MEMORIAL HOSPITAL, BUTH, AND SENIOR SURGICAL REGISTRAR AT THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE

(Concluded from p. 1217)

Discussion of the Various Modern Methods

While most methods of treatment of acute osteitis consist of some form of operative attack on the bony focus with or without some special type of general treatment of the blood condition present there appears to have been only one surgeon who had the courage to ignore entirely the bony focus. This was the late H. Tyrrell Gray, who employed intra-venous mercuric chloride together with anti-staphylococcal or anti-streptococcal serum according to which organism was found on blood culture. Although he did not mention the number of cases he had so treated he stated in 1934 that in the last five years he had lost only one case and that there had been no case of sequestration. He admitted that in desperate cases there was a great deal of anxiety for the surgeon who wished to hold rigidly to these principles of treatment, and while lack of courage alone to face such an anxiety will probably always prevent this form of treatment from becoming popular the principle of disregarding the bony focus does not appear to be sound. As mentioned previously before infection of the bone occurs—that is, before the case actually becomes one of acute osteitis—there is present a mild form of septicaemia but the more severe systemic infection that forms part of the clinical picture of acute osteitis becomes evident only after the development of the bony focus and must be due to the passage of toxins or organisms into the blood stream from that focus a fact that does not appear to be generally recognised and one that calls at once for the immediate treatment of the bone involved. Furthermore the absence of sequestration recorded by Tyrrell Gray after total disregard of the bony focus appears extraordinary for since pus is usually present it seems unlikely that sequestration can be prevented unless it is removed or at the least some means is provided for its escape. Since the Bipp method of treatment is soundly based on the pathology present and will save life shorten the illness prevent sequestrum formation and lead to a minimum of morbidity it is considered that this method provides sufficient reasons for not having to face the anxiety that Tyrrell Gray mentioned.

The value of antiserum and immunisation therapy remains questionable for the results obtained by those who advise and apparently practise them do not appear to recommend their use. It is better however that an open mind be kept on this subject.

It is considered that of general measures by far the most important consists in putting the patient on a balcony where he is in the open air and at the same time can obtain as much sunshine as may be available while nursing food and plenty of fluids are a *sine qua non*.

OPERATIONS

The operative procedures employed in this disease will be discussed in order from the least to the most radical.

Incision of the soft tissues down to the bone—This as a method of treatment is a usually mentioned in connexion with subperiosteal abscess the opening and drainage of this being the only treatment employed. Such an abscess representing as it does a complication due to spread of infection from the bony focus indicates not only delay in diagnosis but suggests that pus is present in the bone. This being so it seems that to ignore that pus means inadequate treatment since its presence in the bone must always be a factor threatening either necrosis because of compression of blood vessels or a more severe blood infection by its escape into the blood stream through the wide valveless veins in the bone. While both Starr (1922) and Holman (1934) favour this form of treatment the latter actually advocates delay in treatment until there is definite evidence of pus formation on the grounds that such conservative measures give the patient a chance to develop some degree of immunity. He states that if the patient is seriously ill and the local signs not well marked, then expectant treatment should be instituted. With this I would agree if I had ever found this combination but in my experience patients who are seriously ill have the local signs only too well marked indicative of a delay in diagnosis that may cost the patient his life. It also shows that the patient's serious plight is due not to the original mild septicaemia that made possible the development of the bony focus but to the severe septicaemia caused through reinfection of the blood stream from the bony focus this forming a potent reason why that focus should be attacked without delay and why early diagnosis is essential to obtain the best results. Holman lost 3 cases out of 31 a mortality of only 9.7 per cent but he states that most of his cases had to have one or more secondary operations for the removal of sequestra thus indicating how prolonged the illness may be that results from this form of treatment. Mitchell (1928) has pointed out that operations for the removal of sequestra are by no means devoid of risk and that prolonged illness lessens the chance of a good functional result. To show that a case treated by this method can heal without sequestrum formation Starr gives as an example a case of acute osteitis of the lower end of the humerus that healed completely in three weeks after operation but unfortunately neither the description of the case nor the radiograms accompanying it would prevent it from having been one not of acute osteitis of the lower end of the humerus but of suppurative of the epitracheal gland. In a later publication Starr (1927) describes a typical case treated by this method. The patient was admitted in May 1922 and had two subsequent operations for the removal of sequestra in September and in December 1923 the wound having discharged during the whole of the time and not healing until two months after the removal of the second sequestrum. A recurrent abscess was opened in March 1924 and healed quickly after drainage was established. Although Starr states that some time after healing examination of the patient showed that there was no deformity and that the function of the leg was normal yet it is difficult to be enthusiastic about a method of

FIG 6A—Acute osteitis of lower end of femur treated by incision of the soft tissues. Radiogram three months after operation to show great thickening of bone and sequestrum

FIG 6B—Same case seven months after operation. The sequestrum has been removed and another has formed. See text and compare with Fig 11

treatment resulting in such a protracted post-operative history

As illustrating a common result of this method of treatment, Fig 6 is of interest. The case was one of acute osteitis of the lower end of the femur treated by incision and drainage of a subperiosteal abscess. The radiogram Fig 6A was taken three months after operation and shows a sequestrum surrounded by recent periosteal bone of great thickness. This was removed and seven months after the first operation—the wound never having ceased to discharge copiously—a further radiogram (Fig 6B) showed that another sequestrum had formed, accompanied by still greater thickening of the femur. So that, after being ill for this length of time, the patient is now faced with the necessity of at least one more operation, will probably have a discharging sinus for several more months, and even at this stage he has a completely ankylosed knee joint.

Another case that came under my notice was one of acute osteitis of the lower end of the fibula which was treated by this method, a subperiosteal abscess being opened and drained. The temperature continued to swing (Fig 7) and the condition of the patient gave rise to much anxiety. Treatment by the Bipp method was then undertaken with a striking result. The chart shows how the temperature came down, pain was abolished, and the patient immediately improved, being quite a different person after his second operation. No further operation was necessary for the removal of sequestra.

It seems that the institution of the Bipp method of treatment at least aborted what would otherwise have been a lengthy illness and may have prevented an even more serious result.

Drilling the bone—Since Starr published his well known paper in 1922, this method of treatment has been widely adopted, although he himself appears to reserve it for cases where no subperiosteal abscess is present. It is one method of bone drainage therapy and, as such, does not appear to be adequate. Even inadequate drainage, however, is better than none at all. It will probably have been the experience of most surgeons that drill holes become occluded almost immediately with purulent debris or granulations and that it is expecting too much of them to drain efficiently even if the dressing, as advocated by Sir John Fraser (1934), consists of gauze soaked in a fluid which theoretically keeps the discharge in solution as it tracks up through the holes in the bone. With this method of treatment the illness is also liable to be prolonged, for judging from the writings of both Starr and Fraser it is not uncommon for sequestration to take place. Starr (1927), for example, reports 207 cases and states that, of these, 26 healed completely without sequestration. These figures mean that sequestra formed in no less than 88 of every 100 cases, a huge percentage and one that compares very unfavourably with that reported above of the Bipp method. Simple trephining of the bone, sometimes carried out, appears to be very little more efficient as a method of drainage than that of multiple drill holes.

While discussing this method of treatment, the following case of acute osteitis of the lower end of the femur is interesting.

When operation was performed a large subperiosteal abscess was found, two large ($\frac{1}{2}$ in) drill holes were made in the bone but no pus was found. Gauze drainage was provided and the wound left open. The temperature chart of this case is shown in Fig 8. A few days after operation the remittent type of temperature indicated a purulent focus that was either not draining or doing so inadequately, while the thigh had become much swollen. The treatment of this case by the Bipp method was undertaken 12 days after the first operation. The wound at this time was about 2 in wide and at operation both drill holes were found plugged with inspissated pus. Gutting of the bone revealed the cancellous tissue of the distal 3 in of the diaphysis to consist almost entirely of pus. Two weeks later the Bipped gauze was removed and the cavity in the bone filled with a pedicled muscle graft from the vastus externus. The rise in temperature

FIG 7—Temperature chart of case of acute osteitis of lower end of fibula treated first by incision of soft tissues and later by Bipp method

midway between the times of the last two operations was due to the development of a subcutaneous pyemic abscess near the left axilla. After the last operation there were two rises of temperature which were not explained, for the patient did not complain of any pain or malaise and examination of the wound and urine showed both to be satisfactory.

Guttering of the bone—This procedure appears to have been brought into disrepute largely through the false impressions about it appearing from time to time these indicating either a lack of appreciation of its proper use or excessive zeal on the part of the operator. Platt (1928) states that upon the conception now proved erroneous by the work of Starr that infection extends along the interior of the bone *pari passu* with the subperiosteal spread the treatment of acute osteitis by the gutter operation was based. While this may be true, it is pointed out at once that the basis of this operation as used in the Bipp method has nothing to do with the question of subperiosteal versus internal spread of infection but has for its foundation the pathological fact that the infection of the bone begins as a small focus which can and should be removed and that the most efficient way in which this can be done is by the use of the gutter operation. Platt further states that where a long gutter has to be made owing to extensive spread of infection this will imperil the viability of the shaft as a whole, that it must tend to add to the amount of necrosis already determined by vascular obliteration and that in bones with a considerable subcutaneous surface the gutter has the disadvantage of leaving an avascular adherent scar. Such anti-gutter propaganda well summarised by Platt has gained much credence and done a great deal to injure the reputation of this operation. In reply to it I would say that the first two statements have not been borne out by my personal experience and that the third describes a condition which can be largely avoided. In 3 of my cases of acute osteitis a gutter

the gutter operation as used in the Bipp method of treatment. In the first place the size of the gutter should be such as to permit of the removal of the infected tissue and no greater. Hence if a gutter only 1 in long is sufficient for this purpose no further increase in its size is necessary or justifiable. There seems no doubt that in times past many gutters have been made indiscriminately without

FIG. 9.—Same case as in Fig. 8. W and one month after the institution of Bipp treatment. It is healed except for two small areas from which there is a little discharge.

FIG. 10.—Acute osteitis of upper end of tibia. Wound three weeks after filling of cavity with free fat graft. Wound healed by first intention. Compare with Fig. 9.

FIG. 11.—Temperature chart of case of acute osteitis of lower end of femur treated first by drilling of bone and later by Bipp method. See text.

over 7 in long necessitating opening into the medullary cavity had to be made in order to reach the limit of the spread of infection. In none of these cases was the viability of the rest of the shaft impaired and there was no sequestrum formation. Where a long gutter has to be made in a bone with a considerable subcutaneous surface if the cavity is allowed to fill up by granulation tissue then an adherent avascular scar will form (Fig. 9) but by using a pedicled muscle graft or free fat graft as described previously a satisfactory scar will be obtained (Fig. 10). Fraser (1934) states that he has abandoned the gutter operation because it did not appear to afford more efficient drainage than that provided by the method of multiple drill holes while the trauma necessarily lessened the reaction and encouraged sequestrum formation. With the first statement I am unable to agree having seen several cases similar to that described in the last paragraph while my answer to the second is to be found in the nearly complete absence of sequestration in the present series of cases.

It would be well, at this point to emphasise certain features which must be borne in mind when performing

any regard to the size of the infected focus with consequent infection of healthy tissue and that this accounts in no small measure for the bad results obtained. Secondly the idea that the gutter operation is synonymous with the opening up of the medullary cavity is an appalling misconception that must be corrected for to do this unnecessarily is asking for trouble and at the same time it indicates ignorance of both the fundamental pathology on which the operation is based and of the technique of its performance.

Furthermore it should be pointed out that acceptance of Starr's contributions to the pathology of acute osteitis in no way contra-indicates the performance of the gutter operation provided this is done in the manner already described and not indiscriminately. The essential difference between the Starr and the Bipp methods of treatment is that while the former seeks to drain the bony focus of infection it is the aim of the latter to remove the focus. The advantages to be gained by removal as opposed to drainage have already been discussed and ample proof of their practical significance is demonstrated by the excellent results obtained in the present series of cases.

Fig. 11 illustrates the results obtained by the Bipp method. They are radiographs from a case of acute osteitis of the lower end of the femur taken one month, six months and fourteen months after operation. The cavity referred to previously under the heading "Length of stay in hospital, the wound being allowed to heal by granulation and the patient leaving hospital 7 days after his admission with the wound completely healed. The cavity of moderate size formed by the guttering of the bone is well shown in Fig. 11a. At the end of six months (Fig. 11b) it is seen to be much smaller while after fourteen months (Fig. 11c) it has been

completely obliterated by sclerosed bony tissue, the structure of the bone itself being almost normal. No sequestrum formation occurred and there has been no thickening due to the formation of new periosteal bone. These radiograms should be compared with those in Fig 6.

Winnett Orr method of treatment—This is placed under a separate heading because, owing to Orr's

FIG 11.—Case of acute osteitis of lower end of femur treated by Bipp method. Radiograms taken one month, six months, and fourteen months after operation. Note absence of bony thickening, gradual obliteration of cavity, and restoration of bony structure almost to normal. See text and compare with Fig 6.

publications (1927) it has become known by his name and seems to have been accorded the status of one which apparently differs from any other. Since, however, it consists of the gutter operation, the treatment of the wound with alcohol followed by iodine, the packing of the wound with vaselined gauze, and the immobilisation of the affected part, its similarity to the Bipp method of treatment becomes at once apparent. At the time, towards the end of the late war, when Orr was formulating his method of treatment, the Bipp method was already established and widely practised in the British Armies. While the principles of this method are the same as those governing the Bipp method—namely, the removal of the bony focus of infection, the use of an antiseptic and immobilisation, and it has the same advantage of obviating the necessity for frequent dressings—yet it is different in one or two important details. In the first place, the iodine as used by Orr will be absorbed in a very short time and no further supply will be available under his method of treatment. The use of Bipp, on the other hand, results in a continuous supply of nascent iodine to the tissues as long as the paste is present in the wound. Secondly, anyone who has had experience of the Orr method need not be reminded of the offensive smell which develops and which makes its use so objectionable. It will be seen, therefore, that the Bipp method of treatment possesses definite advantages over the Orr method in that it is cleaner, more pleasant to use, and is a more adequate means of arresting the spread of infection.

Diaphysectomy—Of this operation I have had no personal experience. Mitchell (1928) reports a series of 13 cases with only 1 death, which indicates that the operation need not be associated with a

forbidding fatality rate, although he does not mention which bones were treated in this manner. Apart from the radical nature of the operation, one objection to it that will always carry much weight is the lack of guarantee of regeneration, the partial or complete failure of which in most of the long bones would lead to considerable deformity and disability. In the rare advanced case in which the diaphysis is found lying loose under the periosteum it could easily be removed but with its removal there would be taken away the best means of ensuring the essential thick involucrum, for the presence of necrotic bone acts as a stimulant to the formation of new bone by the periosteum. The fibula is the only long bone where the question of regeneration does not assume such paramount importance, and four cases of successful total diaphysectomy for acute osteitis of this bone have been reported by Hamilton Bailey (1929). It is felt, however, in view of the results that can be obtained by the more conservative Bipp method of treatment, that diaphysectomy appears to be an unnecessarily radical procedure.

Carrel-Dakin solution—One cannot omit from a discussion of the various methods of treatment of acute osteitis the mention of Carrel-Dakin solution since many bony cavities, the result of the gutter operation, are treated with this antiseptic. It has the advantage of being a more powerful antiseptic than Bipp, but it is very soluble, the effect being so transitory that it is necessary to renew it at frequent intervals. To ensure this renewal special apparatus is necessary, this in its turn requiring attention, the dressings are continually wet, sometimes giving rise to severe irritation of the skin surrounding the wound unless precautions are adopted, and some individuals have a decided distaste for its pungent odour. Bipp, though less powerful, is able to ensure a continuous supply of nascent iodine without requiring renewal for days or even weeks, no special apparatus is necessary for its application, there is usually little or no discharge, and there is no associated smell to upset the patient or his attendants, these features, in my opinion, representing distinct advantages rendering the use of Bipp preferable to that of Carrel-Dakin solution.

Summary and Conclusions

Acute osteitis is a serious disease commonly associated with a high mortality and much subsequent morbidity.

The term "osteitis" is used as meaning the inflammation of any or all of the constituent parts of the bone, and such terms as "osteomyelitis" and "periostitis" are considered superfluous as well as having the disadvantage that they tend to denote separate diseases.

It is important to realise the fact that the disease begins as a small, delimited focus of infection in the cancellous tissue of the metaphysis, for this focus can be completely removed, and that its removal constitutes the rational treatment. While the development of the bony focus of infection presupposes a septicæmia to be already present, this septicæmia must be mild since it gives rise to no symptoms as such. The general symptoms that point to a blood stream infection appear only after the development of the bony focus. In consequence of this sequence of pathological events it is suggested that the severe systemic infection seen in acute osteitis is due to a reinfection of the blood stream from the bony focus, a view that calls for the removal of that focus at the earliest possible moment.

Stress is laid on the necessity for diagnosis in the early stage of the disease—that is before complications due to the spread of infection have occurred. The triad of a *continuous pyrexia intense pain* of sudden onset over the metaphysis of a long bone and exquisite *tenderness* on palpation of the same region associated with a *polymorphonuclear leucocytosis* are the clinical features that appear early and establish the diagnosis.

A description is given of the characteristics of bismuth iodoforn paraffin paste, including its formula, bacteriological and chemical actions.

The principles governing the Bipp method of treatment of acute osteitis and the technique of its performance are described followed by a synopsis of 21 personal cases treated by this method during the past six years. Two cases died giving a fatality rate of 9.5 per cent. one of the lowest on record. Complications were few and the average period of hospitalisation short. The late results concerning growth and function were excellent and a striking feature was the almost complete absence of sequestration. One case is described of recurrence three years after the initial illness.

The various methods of treatment of acute osteitis in use at the present time are discussed in some detail.

In the Bipp method of treatment of acute osteitis the surgeon has at his disposal one for which the following claims are made—

- (1) It has a low mortality rate
- (2) The technique is relatively simple
- (3) It avoids the necessity for frequent dressings
- (4) The dressings themselves are painless a consideration of no small moment in children
- (5) It enables the surgeon to exercise personal supervision of the case instead of delegating this important duty to other people as when frequent dressings are necessary
- (6) It is clean to use and there is no unpleasant associated odour
- (7) No special apparatus is required
- (8) Little or no sequestration occurs thus avoiding the formation of chronic sinuses and the necessity for secondary operations
- (9) Wounds heal in a comparatively short time thus avoiding a lengthy period of hospitalisation and the interference with function so liable to follow a protracted illness involving a limb
- (10) The late results concerning growth and function are excellent

It is considered that the advantages enumerated above to be gained through the use of this method of treatment of acute osteitis merit its wider recognition and adoption.

LEFT INFRAMAMMARY PAIN

A METABOLIC INVESTIGATION

By K. SHIRLEY SMITH M.D. B.Sc. F.R.C.P. Lond.
 PATHOLOGIST TO CHARGING CROSS HOSPITAL AND TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS

A. STEPHEN HALL, M.D. Camb. M.R.C.P. Lond.
 FORMERLY PHYSICIAN TO THE ROYAL CHEST HOSPITAL AND

JOCELYN PATTERSON M.Sc. Ph.D. St Andrews
 CHEMICAL PATHOLOGIST TO CHARGING CROSS HOSPITAL

THAT pain in the centre of the chest or over the left mammary region should suggest heart disease is not unnatural. Indeed many such pains are undoubtedly due to heart disease. It is usually easy to recognise for example the pain of effort angina with its relation to exertion and the prolonged pain of coronary thrombosis. Similarly pain due to acute pericardial disease or to aneurysm is likely to be traced to its true source by careful investigation. There is however another variety of pain over the heart which is commonly called left inframammary pain. It is rather sharply distinguished from the others by its situation roughly over the apex beat its independence of exertion and its good prognosis. In these patients the pain is often the solitary suggestion of heart disease and on examination none of the ordinary evidence of heart disease such as cardiac enlargement arrhythmia valvular disease or high blood pressure is found. The subjects of such pain are usually women suffering from chronic anxiety imagining that they have heart trouble and indeed as the pain is over the place where the heart may be felt beating what more natural supposition than that it is somehow associated with the heart? Yet because of the absence of features of the ordinary recognised heart disease because the pain is unlike those known to be associated with cardiac pathology and because the psychological state of the patient is sometimes abnormal this symptom of left inframammary pain has been consistently dismissed by physicians as "functional."

It may be profitable to consider more closely what is meant by this term. It may mean that symptoms are present and related to disturbances of physiological function which are perhaps not recognisable by the methods at our disposal and which at any rate are not sufficiently gross to be classed as pathological. On the other hand it may mean that symptoms are present that these are unrelated to morbid or even physiological deviation and that the source of the symptoms is psychogenic. The term functional is all too frequently used by clinicians at the present day to embrace both of these groups—the truly functional and the psychogenic. The use of the word functional in connexion with left inframammary pain is fully suggestive to the physician some infirmity in moral fibre in his patient and a lack of significance in the complaint; he therefore feels both unworthy of his attention and the patient is sent away a wreck of a sound heart and the prospect of a long life. Yet the pain persists and has somehow or other to be borne. It is not possible that the patient was originally right in her fears that there is something wrong with the heart and that our methods of examination are so crude as only to discover the gross or forms of disease. May it not be that some disturbance of nutrition as opposed to structural damage is responsible for the production of pain and that there exists in these patients some mechanism correlating their anxious state with metabolic disturbance and pain?

That there is some relationship between a person's psychological structure and the disease to which he is liable there can be little doubt, as witness the observations of Draper (1924), although it is unknown whether that relationship is endocrine or biochemical. There is the excitable temperament of the rheumatic child, the anxious pessimistic man who develops peptic ulcer, and the cheerful optimistic woman who gets gall stones. These associations are so common that they cannot be fortuitous but the links remain to be discovered.

It was in this frame of mind that we began to study patients afflicted with left inframammary pain, subjecting them to clinical, biochemical, radiological, and electrocardiographic investigations, and attempting to find some abnormality that might indicate the link between physical and mental fatigue and the symptom complex of left inframammary pain. In this paper we record the results of our investigations and suggest a working hypothesis of the mechanism of the syndrome.

THE CLINICAL FEATURES

Pain below the left breast is a symptom, common enough in women, which has been recognised for many years and which does not respond to the methods of treatment usually adopted. It differs absolutely from angina pectoris by its lack of immediate relation to exertion. It is situated in its greatest intensity in the neighbourhood of the apex-beat. Frequently the pain is accompanied by liability to palpitation and suspicious (*sighing*) respiration as described by Herz (1910). Associated pain and hyperaesthesia about the angle of the left scapula was first observed by Parkinson (1919). The pain may come on at any time, but is specially apt to occur after physical or mental fatigue. Any exertion that involves stooping or stretching upward with the arms seems likely to produce or aggravate the pain. Characteristically it is a dull ache, but it may be paroxysmal and of extreme severity as described by Gallavardin (1928), the differential diagnosis from spasmodic angina may then present difficulty. Left inframammary pain is not directly relieved by rest. Other symptoms commonly associated are headaches, depression, trembling, and manifestations of vaso-motor instability such as sweating and sensations of heat and cold. In consequence of these the pain is regarded by many physicians as neurotic in origin. In times past it was generally regarded as due to heart disease, and indeed its accompanying phenomena of dyspnoea and palpitations served to emphasise this conception. This pain does commonly occur in heart disease and one of us (Smith 1929) has shown that pain at and below the left breast is a frequent manifestation in congestive heart failure, tending to become more severe with enlargement of the heart and tachycardia. Nevertheless, left inframammary pain occurs much more frequently in patients who have none of the accepted evidence of heart disease, and Baker (1930), in an analysis of 332 consecutive patients at the National Heart Hospital, found this pain complained of in 42.3 per cent of cases with no other evidence of heart disease, and she compiled similar figures in a further series of 266 consecutive patients. Thus a patient with this pain is more likely to have a "normal" heart than not.

EXPERIMENTAL GROUP

The series investigated in the present work comprised 26 patients (all female except 2), who gave left inframammary pain as the main, sometimes the sole, complaint, and who on careful examination by

the usual clinical and cardiographic methods showed no evidence of any recognised form of heart disease. Their ages ranged from 20 to 54. In each instance the patient was admitted to hospital and a very full history was elicited with special reference to the nature, site, radiation and duration of the pain, the associated symptoms, the menstrual cycle, and the presence or absence of factors pointing to anxiety, fatigue, or toxæmia.

Radiological and electrocardiographic examinations were made in each case. An estimation of the fasting blood sugar was made, that is to say, the patient took no food from the evening before until the blood was taken at 7 A.M. Sugar tolerance curves were made in nearly every case, while determination of alkali reserve and the basal metabolic rate by the British Benedict method were made in the majority. Repeated urine tests for acetone bodies were carried out.

Although there are available numbers of statistics relating to the range of the normal fasting blood sugar, it was thought best to study a small series of controls. Accordingly, estimations of fasting blood sugar were made in a group of 11 young women in sound health awaiting various minor orthopaedic operations. Such a group reproduced the condition of hospitalisation of the experimental series and at the same time comprised a number of subjects free from any symptoms or constitutional maladies.

RESULTS

Fasting blood-sugar.—Out of 26 patients—

17	showed	80 mg per 100 c cm or less
11	"	70 mg " " "
8	"	65 mg " " "

In a control series the fasting blood sugars in 11 "normal" female patients had the following values: 98, 89, 87, 85, 85, 82, 80, 79, 75, 73, 71.

Sugar-tolerance curves.—These were obtained in 23 patients. In 9 a peak of 140 mg per 100 c cm or less was found, and in 6 of these the peak was 130 mg per 100 c cm or less. Three curves reached a level of 200 or more. In one of these (peak 230) glycosuria was discovered, in the other two no glycosuria.

Alkali reserve.—Estimations were made in 9 patients and were within normal limits, ranging from 50-77 vols of CO₂ per cent.

Basal metabolic rate.—Investigation of 22 patients, in one of whom it was not possible to obtain a figure.

In 4 patients	it was between	-5% and +5%
In 8	"	+6% and +25%
In 7	"	-6% and -25%

In the remaining two patients values of +28 and +20 were obtained. These patients and some others were regarded as unsatisfactory subjects for the test.

Urine.—Consistently normal in every patient except those two in whom glycosuria was found in association with a reduced sugar tolerance curve.

Body weight.—The patients were with few exceptions spare in build and under weight rather than over weight. This was specially the case in the younger age groups (20-30).

X ray.—Antero posterior telerothograms did not disclose cardiac enlargement or deformity in any case. Generally, the heart was found to be of rather small size.

Electrocardiograms.—The following were regarded as findings that would ordinarily be grouped among normal tracings but which occurred with such frequency among these patients that they have received special attention: (i) T₁ not greater than P₁ in amplitude, (ii) T₂ not greater than P₂ in amplitude, (iii) diphasic T₂ or T₃ with or without (i), or (ii), or (i) and (ii). One or more of these conditions were fulfilled in 16 out of 24 patients. The Figure shows four typical electrocardiograms.

ASSOCIATED FACTORS

- (i) Blood pressures ranged within normal limits
- (ii) Menstrual disturbances or derangements existed

in 14 out of 24 female patients. In 3 of these patients the menopause was in progress (ages between 48 and 54).

(iii) Fatigue in the history—work or special circumstances—in 10.

(iv) Anxiety in 18.

(v) Toxic factors such as excess of tea, coffee or tobacco did not appear to be of any importance.

(vi) Indigestion was conspicuous by its absence in the histories.

DISCUSSION OF RESULTS

It will be seen from the foregoing results that the subjects of left inframammary pain show deviations from the normal in two principal directions. First, an abnormality in the sugar metabolism was found in a high proportion of cases and secondly particular types of electrocardiogram were found with considerable frequency.

Typical electrocardiograms of patient subject 1, left inframammary pain but having no organic disease. Left to right: female aged 43, female aged 48, male aged 43, female aged 45.

Sugar metabolism.—No agreement regarding the normal variations of the fasting blood-sugar and the level below which hypoglycaemia may be said to exist is to be found among the various authorities.

Sigwald (1932) regards 90 mg. per 100 c.cm. as the lower limit of the normal, while Peters and Van Slyke (1931) give 70–120 mg. as the normal range. Graham (1933) and Bourne and Stone (1934) suggest 80–120 mg. while Wright (1930) gives 80–100 mg. Hawk (1931) claims that values below 90 mg. are abnormal and Joslin (1933) names 100 mg. as the limiting low value. Wauchoppe (1933) says that 100 mg. is the normal and that hypoglycaemic symptoms may appear at or below 80 mg. Bendall and Plaqueux (1927) after an extensive survey of the subject concluded that a reading of about 90 mg. or below constituted hypoglycaemia.

The discrepancy between these results depends to some extent upon the diversity of methods used for the estimations. Methods such as the one of MacLean and of Hagedorn and Jensen give on an average readings which are 10–20 mg. lower than those which like Lolin and Wu employ tungstic acid filtrates. Whether capillary or venous blood is examined is of practically no moment in fasting blood-sugar determinations.

In our present series of analyses MacLean's method has been used on capillary blood. Our previous experience of this procedure has indicated that the normal range of fasting blood sugar is from 70 to 100 mg. per 100 c.cm. Thus the 11 cases taken for controls varied between 71 and 98 mg. per 100 c.cm. materially covering the normal range. Since in our

experimental series there were 12 patients with a fasting blood of 70 mg. or less it is seen that approximately half our group were hypoglycaemic whether compared to our own standard of the normal or to the widest range of normal variation given by the authorities quoted above. At the same time the fasting blood sugar in the remaining 14 of our patients fell largely into the lower half of the normal range. Sippe (1933) has found fasting blood-sugar values ranging from 65–77 mg. per 100 c.cm. in four patients complaining of left inframammary pain.

Departures from the normal were also found in the sugar tolerance. The curves in our patients tended to be low and showed an unusually early peak, the estimation at the one hour period being lower than at the half hour stage. On the other hand we discovered the presence of unsuspected glycosuria in one

patient and indisputable hyperglycaemia in two others. It is generally accepted that derangement of sugar tolerance in either direction is the outcome of endocrine disease or dysfunction although the nature of the mechanism is far from being thoroughly understood.

Electrocardiograms.—The special features of electrocardiograms taken from our patients related entirely to the ST segments or T waves. The T waves were found usually to be of less amplitude than the I waves of the same lead and were frequently diphasic or inverted (see Figure). Such changes as these have been recorded chiefly in relation to nutritional or toxic disturbances, and the frequency with which they were found in our series has led us to the view that they are here related in some way to the anomaly of sugar metabolism just described. Similar electrocardiographic variations have been found by Taterka (1930) in diabetic coma by Smith and Hocking (1932) in diabetics. Wittgenstein and Menzel (1924) and Haynal (1935) have made similar observations in hypoglycaemia in diabetes, and a flattening of the T waves has been demonstrated in starvation in children by McCullough (1930). It thus seems likely that the underlying factor in all the cases is a nutritional disturbance of the heart muscle due either to a lack of sugar supply or an inability to metabolise sugar.

Comments.—From the foregoing considerations it is clear that there is a possible basis of relationship to connect the two principal abnormalities found in our investigation. A review of the personal literature

in the experimental group brought out clearly facts which have already been established regarding the subjects of left inframammary pain. Fatigue and anxiety appeared to play an important part not only in the production of the syndrome, but also in determining the frequency and severity of the pain. When physical fatigue and emotional stress operated together, as for example in the nursing of a sick relative, the liability to the pain seemed to be especially great.

MECHANISM OF PRODUCTION

The states of anxiety and fatigue, predisposing to and aggravating the pain, are the outstanding associated factors in the syndrome of left inframammary pain. It must be considered whether there is any possible link to correlate mental or physical fatigue with the group of somatic symptoms which are the subject of the present investigation. Many of the physical manifestations of emotion are so much part of everyday life that except in extreme forms they arouse no comment, others are more subtle and may only be observed by the discerning eye, again, some are too slight to be detected by the observer, and it is in this last field of manifestations that explorations by biochemists and physiologists are beginning to bear fruit.

There can be no doubt that the influence of the emotions on the bodily functions is a profound one, and the literature of this subject has lately been exhaustively explored by Dunbar (1935). But it is upon the endocrine system particularly that emotions seem to exert their most direct effects. Thus Bram (1927) found that in 2842 out of 3343 patients with exophthalmic goitre a clear history of psychic trauma as a cause was obtained. Goodall and Rogers (1933) have made similar observations. The deleterious effects of anxiety upon the diabetic is universally recognised, and Cannon (1929) has found glycosuria at times of anxiety in normal animals and men. Again Williams (1912) has remarked upon the action of chronic fear which he believes to play a part in the genesis of hyperthyroidism and hypo-adrenalism, he has recorded cases in which prolonged stress has apparently led to Addison's disease and death, no other condition than suprarenal atrophy being found at autopsy. Marañón (1929) has reported three similar instances. It should be noted in this connexion that low blood sugar and curves of increased sugar tolerance are the rule in Addison's disease. No record of associations between mental or physical stress and pituitary lesions has been disclosed in a search of the articles on the subject.

The substantial body of evidence indicating the concrete effects upon the bodily functions of emotional disturbances has led us to review our own findings in this light. The salient points in our problem were (i) the existence of a group of symptoms of which left inframammary pain was the chief, (ii) the obvious rôle of physical or mental fatigue in producing or aggravating the syndrome, (iii) a condition in which the blood sugar generally tended to fall to abnormally low fasting levels, and in which a state of increased sugar tolerance was found, and (iv) the prevalence among these patients of particular types of electrocardiogram. It seemed to us most likely that the endocrine system must be the intermediary factor here linking the mental state with the physical. Considering in turn the various endocrine organs, there was in the first place nothing in the literature or in our findings to suggest a pituitary anomaly. The thyroid had also to be rejected on several grounds, first, that in thyrotoxicosis a reduced sugar tolerance is found as opposed to the

increased tolerance seen in the majority of our patients, secondly, our patients presented none of the signs of frank or even masked thyrotoxicosis, and thirdly the basal metabolic rate was found to present no significant deviations from the normal. The conclusion that no thyroid element operated in our patients was supported by the findings of Gallavardin (1935), who in a recent investigation of the comparable syndrome of nervous tachycardia found no evidence of abnormal thyroid function.

The thyroid and pituitary being thus excluded, it remains possible that alterations in fasting blood sugar may relate either to pancreatic or suprarenal causes. Since the tendency of alteration is in the direction of increased sugar tolerance, the glandular derangement would be either in the direction of hyperinsulinism or hypo-adrenalism. As no evidence was forthcoming to suggest the presence of primary hyperinsulinism in our experimental group, we have been led to the hypothesis that in the subjects of left inframammary pain a relative hyperinsulinism frequently exists in association with a state of exhaustion or hypofunction of the suprarenal gland. We suggest that left inframammary pain arises in the heart as the cardiac expression of a metabolic derangement that affects the body as a whole. This metabolic derangement is envisaged as the consequence of endocrine dysfunction brought about by emotional or physical stress. It may be argued that if left inframammary pain is of this origin patients with hypoglycæmia should also be subject to this pain. It is true that precordial pain is not common in hypoglycæmia, but it does occur sometimes as mentioned by Sonne (1929) who also observed palpitation in 44 per cent of cases. This author also refers to the fact that serious symptoms may relate to little fall in blood sugar, while in other cases a sharp hypoglycæmia produces no symptoms. And even though left inframammary pain be related to defective bodily and cardiac nutrition it is not necessarily an invariable accompaniment any more than neuritis is to be found in every subject of diabetes. Moreover, the condition of our patients was not exactly comparable with insulin hypoglycæmia, since in the latter an actual hyperinsulinism exists as opposed to the suggested relative hyperinsulinism in left inframammary pain. It has been observed by Ernestene and Altschule (1931) that hypoglycæmia causes an increased load on the heart since the minute volume is increased during the condition, similar observations have been made by Chasanoff (1929). It seems likely that the explanation of exertional dyspnoea accompanying left inframammary pain lies in these facts.

SUMMARY

1 The syndrome frequently known as left inframammary pain is briefly described. Modern conceptions regarding the nature and source of this pain are discussed.

2 An account is given of an investigation into the clinical features and metabolism of 20 patients suffering from the left inframammary pain syndrome, but from no recognised organic disease in any system.

3 It is found that approximately half of the experimental group showed abnormally low fasting blood sugar, even though the figure of 70 mg per 100 c.c. be taken as the lower limit of the normal. Sugar tolerance curves often showed an increased tolerance, the curves reaching an early, and frequently low, peak. On the other hand, in two patients an unsuspected diabetes was brought to light, and in three others hyperglycæmia without glycosuria.

4 The electrocardiogram in the subject of left inframammary pain is found frequently to show certain features hitherto regarded as normal.

5 Examination of alkali reserve basal metabolic rate and heart size by radiography shows no abnormality.

6 The nature and origin of left inframammary pain are discussed. It is suggested that this pain is the cardiac expression of a metabolic derangement that affects the body as a whole. It is further suggested that this disturbance is related to an underlying endocrine imbalance.

A NEW MACHINE FOR THE SELF ADMINISTRATION OF GAS AND-OXYGEN ANALGESIA IN LABOUR

By ADAM BARR, M.B. Class, F.R.F.P.S. M.O.G.
 SENIOR ASSISTANT TO THE HONORARY PROFESSOR OF MIDWIFERY
 UNIVERSITY OF GLASGOW, VISITING SURGEON TO THE
 GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL,
 VISITING OBSTETRICIAN AND GYNAECOLOGIST TO
 STOBHILL GENERAL HOSPITAL, GLASGOW, AND

ANDREW TINDAL, M.B. Class
 VISITING ASSISTANT TO THE WESTERN INFIRMARY AND THE
 ROYAL HOSPITAL FOR SICK CHILDREN, GLASGOW,
 AND TO THE GLASGOW DENTAL HOSPITAL

DURING the past few years many attempts have been made in response to a growing demand from all sections of the community to evolve some safe method of producing relief from pain during labour.

In domiciliary practice the majority of women go through the greater part of labour with no mitigation of pain. Most practitioners administer during the second stage of labour intermittent chloroform anaesthesia. Nevertheless this is not the stage at which the patient is most in need of relief. Observation and examination reveal that the most fatiguing and certainly the most painful part of labour is the latter part of the first stage—and it is at this stage that relief is demanded—the pains are increasing in intensity and yet the patient feels that the present stage is not progressing and she can do nothing to help herself. Prolonged intermittent chloroform anaesthesia is obviously because of late dangers inadvisable at this stage and to this must be

added the disadvantages that labour is delayed and the incidence of forceps delivery is increased. Administration of sedative drugs because of their uncertainty of action, a so-called restlessness and possible effect on the child has never been a popular method of relieving pain in domestic midwifery practice.

The community and the profession are indebted to Minnitt who in 1934 devised an apparatus for the self-administration of nitrous oxide gas in air to produce analgesia. Although this has not proved entirely satisfactory in use it has become obvious that future developments in this method should prove the ideal means of producing analgesia in labour. Administration of nitrous oxide gas and

air or oxygen possesses advantages over all other methods in that while it relieves the pain of labour it is in no way dangerous to the mother or the child nor does it prolong labour—the frequency of contractions is not interfered with and the strength of contractions is not diminished. The incidence of instrumental interference therefore should not be increased.

During the past two years we have endeavoured to evolve an apparatus which would fulfil certain conditions which we considered essential if it were to be of value in general practice midwifery. It must (1) be safe and foolproof (2) deliver a fixed proportion of nitrous oxide gas and oxygen (3) be low in initial cost (4) be low in running expense (5) be compact and easily portable (6) have a minimum of moving parts to go out of order and have a mechanism which is easily understood (7) if possible be capable of producing some degree of analgesia at the moments of birth. After much experimenting constructional and clinical we have produced such an apparatus.

Essentially it consists of a rubber bag of 10 gallons capacity. Two tubes enter this on leading, first from a nitrous oxide cylinder and the other from an oxygen cylinder. In order to measure the oxygen a 1 gal rubber bag which has a tap at either end is connected up as in the Figure. Two corrugated rubber tubes lead from the bag to the face-piece—directional valves are fitted so that the gas mixture in the bag is inured through the tube and the expired breath is exhausted into the bag. A valve is incorporated in the face-piece in such a way that when the plunger which keeps the face-piece pressed against the face is released the flow of gas and oxygen is automatically stopped and air only is breathed.

METHOD

The procedure is as follows. All air in the bag is expressed by rolling them flat at the same time depressing the plunger on the face-piece. The tap (4)

proximal to the oxygen bag (capacity 1 gal.) is closed and the distal one (B) opened, and the bag then filled with oxygen. This small bag, which now contains 1 gal. of oxygen, is emptied into the reservoir by opening the proximal tap and squeezing the bag. The tap (A) is then closed. The reservoir, which now contains 1 gal. of oxygen, is then filled to capacity with nitrous oxide to a point just short of stretching the rubber. The tap between the cylinder and the reservoir is now closed. The reservoir now contains approximately 10 gal. of gas—90 per cent nitrous oxide and 10 per cent oxygen.

The apparatus is now ready for use. Whenever the approach of a pain is appreciated, the patient expires to the fullest extent, then placing the face piece over her nose and mouth, presses the plunger valve and takes a long inspiration from the reservoir—the following expiration passes back into the reservoir. She continues in this manner until the contraction is over, when she releases her grip on the plunger and removes the face piece. The apparatus is ready for the next pain. One filling may last from $\frac{1}{2}$ to 2½ hours, depending upon the frequency of the pains. It will be observed that as time passes the reservoir tends to sag. Before it is completely emptied, its contents, now diluted with exhaled air, are expressed by folding the reservoir flatly and depressing the plunger as before. It is then refilled as in the beginning.

The concentration of nitrous oxide permits sufficient analgesia of rapid onset, and the 10 per cent oxygen is sufficient to prevent anoxæmia. The concentration of carbon dioxide in the reservoir never becomes high enough to cause any divergence from the normal rate of respiration.

The apparatus is manipulated by the patient herself, an attendant being required from time to time to refill the bags.

If sufficient relief from pain is not obtained for the actual birth of the head, the nurse or medical attendant may, by applying the face piece continuously with the plunger depressed, obtain adequate analgesia for this purpose. The same procedure will allow of episiotomy or insertion of perineal sutures.

Our experience has been that where the analgesia is begun early enough, the patient becomes so expert in the use of the apparatus and so assured of relief from pain that she frequently sleeps naturally between pains, only waking sufficiently to reapply the face piece at the beginning of the next contraction.

This form of analgesia can be carried on indefinitely, one of our cases lasting over thirty hours with no ill effects.

RESULTS

In order that the degree of analgesia produced by this machine might be accurately estimated, we have adhered to certain standards throughout our investigations. (1) The cases here reported were delivered in one institution where certain nurses were instructed in the use of the machine or, in private practice, by ourselves. (2) In order that the actual relief from pain might be correctly assessed, no preliminary sedative drugs were administered in any case. (3) In each case a record was kept of the effects of the gas noted by the nurse in attendance, and also of the opinion expressed by the patient herself at the time of labour.

A total of 100 cases were treated. Of these 20 were not aware of the birth of the child and voluntarily expressed surprised relief that the labour was concluded. There were 20 patients who were extremely nervous when the treatment began, and 12 of these became calm and controlled, cooperating readily shortly after they realised the effect of the gas. 8 of these 20 cases, however, proved

unsatisfactory, throughout because of a lack of self control or an inability to obey the instructions for using the apparatus—it seemed noteworthy that none of these occurred in our private practice where co-operation was intelligent. After a very satisfactory analgesia in the first stage, 3 multiparæ preferred to dispense with the apparatus during the second stage on the plea that labour was being delayed, although there was no diminution in the force and frequency of the uterine contractions—this seemed to us an argument for the efficiency of the analgesia. The remaining 48 patients had a very good relief from pain although they felt the actual birth of the child. There were 6 cases of forceps delivery for reasons not associated with the analgesia—persistent occipito-posterior position and contracted pelvis—chloroform was administered in these cases for delivery.

There were no stillbirths in the series and no neonatal deaths, and in all the child cried vigorously at birth. At no time was cyanosis observed other than the discoloration which is normal in the downbearing of the second stage of labour.

COMPARISON WITH OTHER MACHINES

In 1935 a committee of the British College of Obstetricians and Gynaecologists reported on an investigation into the use of analgesics suitable for administration by midwives. The records of almost 4000 patients who received analgesia from the Minnitt apparatus (35 per cent nitrous oxide in air) were considered. In 23 per cent of these cases the analgesia was reported as either doubtful or unsatisfactory.

Chassar Moir (1937) has recently expressed his disappointment, which confirms our own experience, at the meagre benefits which this type of machine, delivering 35 per cent nitrous oxide in air, confers, and has shown that the inefficient analgesia results from the inability of many women to inhale a sufficient amount of nitrous oxide before the full force of the uterine contraction is upon them. In his apparatus, pure nitrous oxide gas sufficient for two deep breaths is delivered from a reservoir. In the apparatus here described, 10 per cent oxygen is added to nitrous oxide gas, and the patient is able to obtain sufficient analgesia for even the prolonged and severe uterine contractions which are typical of the second stage of labour, without fear of anoxæmia.

The apparatus is very moderate in price, light in weight (24 lb.), and can be used at a cost of from 3d to 6d per hour. No mechanical adjustments are necessary—the principle on which it operates is obviously simple. (Many nurses and practitioners have expressed to us their feeling of insecurity when working with complicated machines the mechanism of which they do not understand.)

SUMMARY

A new machine for obtaining analgesia by means of nitrous oxide gas and oxygen is described. It is cheap, easily portable, and foolproof in use.

A series of cases is described in which 92 per cent obtained a satisfactory analgesia—in 20 per cent a perfect analgesia.

Less than 10 per cent proved unsuitable—a more or less irreducible minimum with a certain unintelligent and nervous type of patient who is always troublesome with any form of inhalational anaesthesia.

The apparatus is assembled and distributed by the British Oxygen Co., Ltd., Polmadie, Glasgow, and is known as the Tindal Barr Analgesia Apparatus.

CHEMOTHERAPY OF STREPTOCOCCAL INFECTIONS WITH *p*-BENZYLAMINO BENZENE SULPHONAMIDE

By B A PETERS M.D. Camb. D.P.H.

MEDICAL SUPERINTENDENT TO THE HAM GREEN HOSPITAL AND
BAXTERIANUM, BRISTOL AND

R V HAYARD M.R.C.S. Eng.

ASSISTANT RESIDENT MEDICAL OFFICER, HAM GREEN HOSPITAL
AND BAXTERIANUM, BRISTOL

During the past winter 150 cases of scarlet fever 47 cases of erysipelas and 18 cases with other types of streptococcal infection were treated with Prospectasin (*p* benzylamino benzene sulphonamide) an ample supply of which was placed at our disposal by the makers Messrs May and Baker

SCARLET FEVER

In the scarlet fever test group no antitoxic serum was given. As controls 150 alternate cases were treated with serum when considered necessary (58 cases) and the remainder expectantly. The dose given was 0.75 to 6 g. per day according to age by mouth in tablet form divided into four hourly doses. The full dose was given for two days, and half the quantity for another two to four days according to the course of the illness. The maximum quantity given in all to any one patient was 22.5 g. The results are shown in the Table.

It will be observed that in the test series, 53 (35 per cent.) developed one or more of the complications tabulated whilst 84 (56 per cent.) of the control cases showed some complications. This difference is statistically significant. The sum of the individual complications is almost identical but the complications in the test series occurred in fewer patients. The mean duration of the primary fever from onset to termination was twelve hours longer in the test series. Since antitoxin was administered to a third of the control series this might be expected for antitoxic serum undoubtedly reduces pyrexia. Our

results would suggest therefore that the drug has some effect on the invasive side of this streptococcal infection and the results might be better if the drug could be given earlier. If spaces such as nasal sinuses the middle ear or bone are infected the organism is probably less accessible to the drug. Possibly a combination of drug and serum would be more effective and this is now being investigated.

ERISIPELAS

The results here were very striking. A series of 47 cases of erysipelas of varying severity from mild to very severe, was treated with similar doses of the drug. The youngest patient was four months three were 70, 81 and 87 respectively. In 31 cases the temperature was normal within twenty-four hours in 12 within forty-eight hours in 3 within seventy-two hours, and in 1 only did pyrexia continue until the fifth day. The spread of the disease was arrested within twenty-four hours in every case. Two developed relapses ten days after the primary attack which responded at once to further doses of the drug. All the cases made satisfactory recoveries even the aged ones.

OTHER STREPTOCOCCAL INFECTIONS

In 15 severe cases of tonsillitis notified as diphtheria there was recovery within forty-eight hours of treatment with the drug.

In one case of puerperal sepsis showing signs of early involvement of the broad ligament which gave a pure growth of hemolytic streptococcus from the cervix the temperature settled within eighteen hours and the patient made an uninterrupted complete cure with rapid resolution of the infiltrated broad ligament.

One very ill patient with cellulitis involving the fauces arising from an impacted wisdom tooth lost his fever within seventy-two hours and recovered.

In one case of influenza pneumonia with a turbid pleural effusion from which a pure growth of hemolytic streptococci was cultured the effusion dried up after two aspirations following the administration of the drug and the patient recovered. In our former experience such effusions invariably became purulent and necessitated operation for cure.

1 case of nephritis developed uremia

† Abdominal pain died after exploratory laparotomy following perforation of the appendix

TOXIC EFFECTS

One child with erysipelas developed a macular rash, two very fat women complained of nausea and vomited once, no case showed any cyanosis or clinical signs suggesting sulphæmoglobinæmia. It seems, therefore, that the drug produces few toxic symptoms in the doses we gave and is well borne at all ages.

SUMMARY

The administration of prosectasine to scarlet fever patients reduced the number of patients having complications from 56 per cent. in the control series to 35 per cent. The drug seems to affect chiefly the invasive stage and results might be better if it could be given earlier.

In erysipelas the spread of the disease was arrested in 24 hours in all of 47 cases. In 31 cases the temperature was normal within 24 hours and in a further 12 within 48 hours. A similar result was seen in other types of streptococcal infection.

SOME OBSERVATIONS ON A CASE OF PULMONARY OEDEMA

BY GEORGE GRAHAM, M.D. Camb., F.R.C.P. Lond.

PHYSICIAN, ST BARTHOLOMEW'S HOSPITAL, AND

RONALD BURN, M.R.C.S. Eng.

WE have made two observations on a patient with pulmonary oedema which seem so important that we are recording them now, as it may be long before we have the opportunity of making detailed investigations on another patient with this condition.

The patient, a woman aged 64, has been seen at intervals by one of us (G.G.) since 1925. In that year she developed the symptoms of a mild toxic goitre, and was treated by Sir Thomas Dunhill with rest and iodine. Glycosuria and hyperglycæmia were also present at that time, and were treated with dietetic restrictions and insulin. The symptoms abated, and after two to three years did not cause any further trouble. The diabetic condition improved greatly with insulin, and she was able to take 180 g. of carbohydrate without insulin in 1928. Since then the diabetic condition has become worse and in January, 1936, she needed 18+16 units for a diet containing 130 g. of carbohydrate. At that time she was complaining of lassitude and had a slight degree of pyrexia. No cause for this fever was discovered and the temperature gradually decreased and the symptoms abated. In March she was again feeling unwell with slight pyrexia and then had an acute attack of *B. coli* pyelitis, which lasted for five weeks. An intravenous pyelogram showed that she had a large cyst of the kidney, which was thought to be congenital. The *B. coli* infection was at first treated with alkalis and later with mandelic acid. The symptoms were quickly relieved with mandelic acid but it was not until August that the urine was rendered sterile.

Her general health had greatly improved, but she was still easily tired, and was only up for about five hours in the day. She had occasionally noticed a little wheezing and tightness of the chest when falling asleep.

On Dec. 1st, 1936 she had a slight coryza, and on Dec. 4th at midnight a feeling of tightness of the chest. This was followed at once by an acute attack of pulmonary oedema. She became ash grey in colour, P 140, R 36, B.P. 180/100. Many râles were heard over both lungs, but there was little expectoration. She was given at intervals injections of Asthmolyan 1 c.cm., atropine sulphate gr. 1/100, Coramine 2 c.cm., and atropine gr. 1/150. The acute attack lasted about two hours and she gradually recovered. She was seen two days later by Sir Maurice Cassidy, who agreed that the attack was one of acute pulmonary oedema. The electrocardiogram was quite

normal. She was kept in bed for 4 weeks but was then allowed to resume her ordinary convalescent life. She still had a slight pyrexia (99-99.5° F.). Blood pressure was 160 to 180/80, hæmoglobin, 82 per cent. colour index, 0.7, red cells, 5,600,000, and white cells, 23,000.

On Feb. 6th, 1937, she had another acute attack which started suddenly at midnight. The respiration was 40, pulse 144. Many râles were heard all over the lungs and there was again little expectoration, but she vomited several times. She was given at intervals coramine 2 c.cm., morphine gr. 1/6, atropine gr. 1/100, coramine 2 c.cm., atropine gr. 1/150. The attack passed off in about 2 hours. She was very unwell the next day, vomiting several times and passing a great deal of sugar in the urine, and was seen by G.G. on this account. The following were the results of examinations made of the blood: sugar, 230 mg. per 100 c.cm., urea, 52 mg. per 100 c.cm., alkali reserve, 63.5 vols. (Dr H.E. Archer).

The blood urea had been estimated several times during the previous illness and was usually between 32 and 36 mg. per 100 c.cm. The rise to 52 mg. suggested that the kidney might have failed because of the acidæmia which was probably present during the acute attack of dyspnoea. As both the attacks started so suddenly the possibility of her being sensitive to some substance was considered. Her rooms were always full of flowers, but no unusual flower had been brought into the rooms in the last few days.

A week later the general condition was better. The blood urea was 32 mg. per 100 c.cm. and the diabetic condition was under much better control with 22+23 units of insulin. The blood pressure was 170/80. The patient was allowed to get up after tea on this day, and while walking in her room complained of a tight sensation in her chest. She was put to bed at once and given, at 5.50 p.m., morphine gr. 1/2, atropine gr. 1/50, adrenaline 0.5 c.cm. In spite of this treatment the symptoms developed rapidly, and when she was seen by R.B. at 6.5 p.m. was in great distress. She was given, at 6.5, coramine 1.7 c.cm., at 6.20, morphine gr. 1/6, atropine gr. 1/100, at 7.10, atropine gr. 1/100. The blood pressure was 200/80, a rise of 30 mm. from the morning. The pulse rate was 140 and feeble, and the respiration 46. Moist râles were heard all over both lungs. During the next one and a half hours she vomited two or three times, bringing up a good deal of fluid. Two hours after the onset she was seen by G.G. The attack was then passing off, although she was still very ill. The respiration was 40 and the pulse 140, moist râles were heard all over the lungs. Ten c.cm. of blood was collected at this stage for analysis. An injection of adrenaline 0.5 c.cm. was then given subcutaneously, after ascertaining that the point of the needle was not in a vein by first withdrawing the plunger of the syringe. Ten minutes later the breathing was quieter and she said she felt better. The blood pressure at this stage was 170/100, pulse rate 144. Half an hour later another 0.5 c.cm. of adrenaline was injected, using the same precautions and the condition continued to improve. An hour later she was well enough to be left although the pulse was still 120 and the blood pressure 170/80.

When the estimation of the blood-sugar was made that night it was noticed that the blood flowed up the pipette with difficulty. This condition had been observed before in a case of diabetic coma (Graham, Spooner, and Smith 1926) and a week previously in a case of severe vomiting after influenza (G.G.). The hæmoglobin was estimated at over 130 per cent. on a Sahli apparatus, and the next day by Dr H.F. Brewer using a standard Haldane apparatus, at 135 per cent. When the blood had stood for a while the amount of plasma was very small compared with the number of red cells, but a hematocrit estimation was not made. The alkali reserve was 49 vols., blood urea was 36 mg. per 100 c.cm., and blood sugar 260 mg. per 100 c.cm. The hæmoglobin had been 82 per cent. in January and two days after the attack was 80 per cent.

DISCUSSION

The two observations to which we wish to draw attention are the rise in the blood pressure and the increase in the hæmoglobin percentage, as we believe they may throw light on the cause of the condition.

One hypothesis regarding the etiology of pulmonary oedema is a failure of the left heart and this is supported by the experiments of Welch (1878). He showed that partial obstruction of the aorta caused oedema of the lungs. The rise of the blood pressure in the brachial artery in our case and the statement by Hamman (1934) that the attacks are often preceded by, or at least accompanied by a marked rise of blood pressure, a so called blood pressure crisis, shows that a failure of the left heart in the ordinary sense does not cause the attack. The high blood pressure might be associated with some obstruction distal to the brachial artery. Such an obstruction occurs in wound shock but pulmonary oedema is not a feature of this state. This evidence suggests that the left ventricle and presumably the left auricle are not to blame.

The only structures between the lungs and the left auricle are the intra and extra pulmonary veins. A contraction of these veins somewhere between the lung capillaries and the left auricle would make the return of the blood to the left auricle very difficult and would cause an outpouring of fluid into the alveoli of the lungs. All those who have made experiments on the pulmonary circulation of animals have found that any interference with the pulmonary veins leads to the early onset of oedema of the lungs. The outpouring of fluid into the lungs would deprive the blood of plasma and explain the rise in the percentage of hemoglobin from 80 to 135 in the peripheral circulation in our case. The blood would become much more viscous and be more difficult to drive round the circulation and cause a rise in the blood pressure at first. Another point in favour of this hypothesis is the improvement in the clinical condition which was noticed after the injection of adrenaline. This was given with the idea of relieving any spasm of the bronchi which might be present and thus easing the breathing. The improvement may have been due to another cause. In recent years many experiments have been made on the pulmonary circulation but they are difficult to carry out and the results are not easy to interpret. Gaddum and Holtz (1933) made their observations on lungs which were not ventilated but were perfused at a constant pressure. Adrenaline caused an increase in the outflow from the lungs in five out of ten cases and a decrease in two cases. Alcock Berry and Daly (1935) who ventilated the lungs, showed that a minimal effective dose of adrenaline generally caused an increase in the venous outflow with little or no change in the pulmonary artery pressure. Larger doses tended to raise the pressure considerably without causing a comparable increase in outflow.

We have recorded these observations in the hope that others who have the opportunity may make extended observations on this condition. If the following routine were adopted our hypothesis could easily be proved or disproved.

(1) An injection of morphine tartrate gr $\frac{1}{4}$ should be given at once since all observers seem to agree on its value.

(2) The collection of 1 to 2 c.cm. of blood in an oxalate tube. This should be done as soon as possible and repeated every 15 to 30 minutes until the attack ceases. The hemoglobin hematocrit value red and white cells should be estimated in each sample.

(3) The estimation of the blood pressure at frequent intervals.

(4) The injection of adrenaline 1 c.cm. subcutaneously. The plunger should always be withdrawn to make certain that the point of the needle is not in a vein.

If the attack is not very serious it will probably be sufficient to repeat the injection every 15 or 30 minutes until the attack is over. If the attack is very severe the dose should be increased to 2 c.cm. and perhaps given at more frequent intervals, but we have not sufficient data from our one case to determine the point.

ACUTE ASCENDING FLACCID PARALYSIS

By J SHAFAR, M.B. Glasg. D.P.H.

RESIDENT MEDICAL OFFICER WEST END HOSPITAL FOR NERVOUS DISEASES, LATE HOUSE PHYSICIAN TO THE HOSPITAL OF ST JOHN AND ST ELIZABETH, LONDON

Cases of acute ascending paralysis are sufficiently rare to merit individual publication. Moreover differences exist between authorities as to the correct classification of these cases.

Landry in 1859 published a report of a patient in whom there was acute flaccid paralysis beginning in the periphery of the lower extremities and which spread rapidly upwards involving the arms, trunk and respiratory muscles, death ensuing from respiratory failure. No objective sensory changes were present. Examination of the spinal cord and brain failed to reveal any gross abnormality macroscopically or microscopically. The term Landry's paralysis has since then been used to describe such cases.

Giving the name of Landry's paralysis to all types of acute ascending paralysis of a lower motor neurone variety by some and its limited use by others has led to some confusion. Collier (1933) considers the distinction between Landry's paralysis and acute polyn neuritis to be an artificial one based on the presence or absence of objective sensory disturbance. He regards the sensory changes as an expression of the peculiar selective capacity of the poison and points out the not uncommon case of polyn neuritis with no objective alterations in sensation. Russell Brain (1933) similarly holds that Landry's paralysis and acute polyn neuritis are identical. Drake (1935) accepts as Landry's paralysis any acute ascending paralysis of a lower motor neurone type irrespective of the etiology—syphilis, infectious diseases, poliomyelitis, &c.

According to Goldby (1930) there are three forms of this variety of paralysis. He has collected and tabulated in all 54 cases. In the first group he places those cases in which there is little or no febrile reaction and in which post mortem examination reveals few if any changes. This group is almost exclusively confined to males in its series and occurs usually during the third decade of life. Sphincter control is nearly always preserved and sensory changes are subjective; the etiology is unknown. In the second group an acute paralysis of the lower motor neurone type ascends symmetrically on both sides of the body as in the first group but this subdivision is characterized by objective as well as subjective sensory changes and post mortem changes in the parenchymatous and interstitial tissue of the nervous system. Sphincter trouble is more common than in the first group although the age incidence is

much the same. An important feature is the general toxæmia present. *Ætiologically* this group is closely related to acute polyneuritis. The third group comprises those cases in which the post mortem findings are very similar to those of poliomyelitis. In such cases the paralysis is preceded or accompanied by a febrile illness and clinically signs of increased intracranial pressure with meningeal irritation are present.

CASE REPORT

The following is an account of a fatal case of acute ascending paralysis in a girl of 14½ years.

The child was admitted at 8 P.M. on Oct. 15th, 1936, and died at 3 o'clock next morning. In infancy she had had chicken-pox, measles, and whooping cough. She was an only child and still at school, where there were other children ill with "colds," and others absent on account of illness. She was perfectly well until her present condition. Her father and mother are alive and well. She had been well until 12 days before admission when she developed a headache over the frontal area. With this headache there was a sense of congestion in the nose, which however did not actually run. No sore throat was complained of. She went to bed on the same day and the headache did not abate. A severe pain in the back of the neck began 2 days later, this was continuous but it disappeared on the day before admission. The headache also persisted and was present until the day before admission. Her lower limbs became weak 8 days after the beginning of the illness. This weakness increased until she was unable to move them. Next day her upper limbs became similarly affected and difficulty in breathing commenced. At no time was there any pain in the limbs. There had been no incontinence of urine or feces, no rigors, diplopia, or convulsions. Insomnia had been severe.

On admission her temperature was 99.5° F., respirations 40, and pulse rate 105. She was a well-developed and very intelligent child. She answered questions clearly and was able to give a lucid account of her condition. The face was flushed and the alæ nasi working markedly. The lips were cyanosed. Pulse regular in force and rhythm. Tongue coated.

Central nervous system—Pupils equal, regular and central reacting to light and accommodation. Vision and fields of vision unimpaired. The eyeballs move in all directions with no sign of muscle weakness or nystagmus. Corneal sensitivity and sensation in the face apparently normal. Some paresis in left lower face, but no actual paralysis. There was no difficulty in speaking or swallow-

ing, and the palatal muscles moved well and equally on both sides. Tongue protruded in midline, jaw muscles unaffected. The muscles of the neck were paralysed and the patient was unable to move her neck in any direction at all. Considerable pain was elicited on passive flexion of the neck which was very rigid.

Both upper limbs were in an advanced stage of paralysis, the right more than the left. On the left, slight flexion and extension of fingers and wrists, and very limited extension of forearm were present. The right arm showed

FIG. 2.—Dorsal cord anterior horn (hematoxylin and eosin) showing perivascular cuffing and edema and a collection of microglia cells ($\times 520$).

some degree of flexion and extension of the left foot and extension of the left knee. The right leg appeared completely paralysed. The muscles of the lower limbs were very hypotonic, reflexes present and equal on both sides, plantar responses flexor, no sensory loss in either leg.

Throat—Generalised inflammation. Signs of left follicular tonsillitis.

Chest and abdomen—Normal.

Lumbar puncture—Clear, colourless fluid, pressure 130 mm. Pathological report on cerebro spinal fluid—

Total cells	14 per c mm (lymphocytes)
Globulin	A trace
Total protein	0.025 per cent
Chlorides	0.676 "
Sugar	Normal
Lange's gold curve	0 0 1 2 2 2 0 0 0 0

The stained specimen revealed no organisms and cultures remained sterile after 7 days.

Progress—The dyspnoea and cyanosis became increasingly worse. Just before death the temperature became subnormal and the pulse rate dropped to 78.

A post mortem was performed and the cord and brain removed under aseptic precautions. Portions of the cord and brain at varying levels were submitted for pathological examination, while similar portions were dispatched to the Lister Institute of Preventive Medicine.

Pathological report—To the naked eye the pial vessels were engorged, especially over the cord and brain stem. The cord was soft and oedematous, but showed no gross softening. Portions of the cord were taken at all levels and from the mid brain and cortex, and were fixed in 75 per cent alcohol and 10 per cent formal saline. The sections, stained with

Lehmann's stain and hematoxylin and van Gieson's, showed that no portion of the cord had escaped severe damage. The large anterior horn cells, particularly in the lumbar and cervical enlargements, were greatly reduced in number. Some were degenerated, with swelling of the cytoplasm, disappearance of Nissl's granules, and necrosis of the nucleus. Round about these degenerated nerve cells there was considerable focal glial reaction. Cell nests of microglial cells, many of them rod shaped, were visible in some of the sections.

FIG. 1.—Lumbar cord anterior horn (Lehmossok's stain) showing destruction of large anterior horn cells ($\times 160$).

ing, and the palatal muscles moved well and equally on both sides. Tongue protruded in midline, jaw muscles unaffected. The muscles of the neck were paralysed and the patient was unable to move her neck in any direction at all. Considerable pain was elicited on passive flexion of the neck which was very rigid.

Both upper limbs were in an advanced stage of paralysis, the right more than the left. On the left, slight flexion and extension of fingers and wrists, and very limited extension of forearm were present. The right arm showed

Virohow Robin spaces showed oedema and congestion with perivascular cuffing. In many areas minute capillary hemorrhages were visible about the vessels. In the lumbar region there was destruction to the central canal of the cord and much congestion of the pia and nerve roots (Figs 1 and 2). The spleen and lymphatic tissues in the ileum were not examined.

Animal inoculation.—At the Lister Institute an emulsion was made of the material sent and 1 c.c. injected into the brain of a monkey on Oct. 17th. The monkey remained well until Oct. 23rd when it seemed lethargic and its movements became weak and incoordinated. Next day the condition was much worse and the animal was unable to eat. It remained huddled up and immobile in a corner and when disturbed only moved with great difficulty. On Oct. 26th it was very ill indeed and the weakness was even more pronounced. The temperature was well below normal. The animal was not expected to survive the day and so was killed. The brain and cord were removed and sectioned but nothing abnormal was found beyond slight congestion of the meninges and brain surface. The other organs revealed no abnormal findings. The monkey's brain was then emulsified with portions of the cord at various levels. 1 c.c. was injected directly into the brain of a second monkey and 1 c.c. of emulsion which had been filtered into the brain of a third. Neither injection produced any effect on either monkey, both being alive and well two months after the inoculation. Then into the brain of two rabbits was injected 1 c.c. of the emulsion obtained from the brain and cord of the original monkey. Neither inoculation was subjected to previous filtration. One rabbit died and again autopsy failed to reveal anything abnormal in the central nervous system or other organs. The other rabbit remained unaffected. From the rabbit which died the brain and cord were emulsified and injections were made intracerebrally into two other rabbits which are alive and well six weeks after inoculation.

COMMENTS

Dr G. H. Eagles who has kindly performed the inoculation work states that the first monkey which died did not behave at all like a case of poliomyelitis. The restlessness, nervousness, and apprehension found in monkeys suffering from poliomyelitis were absent, as was the high pitched cry which is so typical. There also was no flaccid paralysis in any of the monkey's limbs.

An inquiry was made whether there was any poliomyelitis in the district in which the girls' school and house were situated. The M.O. of that area had received one notification only during the whole of 1936.

The case is singular in some respects. A period extending over eight days of generalised symptoms preceded the onset of the paralysis. The throat showed definite inflammatory changes and it is possible that this was the origin of the toxin—if toxin it was—that caused the changes in the central nervous system. Pathological changes were very considerable in the sections of the spinal cord of the girl, this being very unlike the usual negligible post mortem findings of the cases described originally by Landry. Also the case does not fit in with a diagnosis of poliomyelitis because of the clinical picture and behaviour of the animals inoculated with an emulsion of the spinal cord and brain.

My thanks are due to Dr. Eagles for the inoculation work at the Lister Institute and to Dr. Redvers Ironside for the pathological report and for his very kind advice.

LYMPHATIC LEUKÆMIA WITH BILATERAL MAMMARY CHANGES

REPORT OF A CASE

By B. JOAN HARAM M.R.C.S. Eng.

ASSISTANT PATHOLOGIST, ELIZABETH GARRETT ANDERSON HOSPITAL, LONDON

The patient, an unmarried woman of 39, was first seen on April 7th 1936, when she complained of a swelling in the left breast of three months' duration. It had gradually increased in size and was associated with neuralgic pain. There had been no discharge from the nipple and no pain in the breasts during the menstrual periods.

Past history.—A small swelling, thought to be a cyst, had been removed from the right breast ten years previously. Apart from curettage for dysmenorrhœa in 1927, a "nervous breakdown" in 1935 and a tendency to winter coughs, the patient had always been healthy.

Clinical findings.—The left breast was seen to be larger than the right and a mass was visible in the upper quadrant. The nipple was not retracted. On palpation a tumour about the size of a very large hen's egg was felt in the upper part of the breast, attached to skin but not to deep structures and a hard gland was palpable in the left axilla. The chest was radiographed and no evidence of secondary growth was found, but there was some fibrosis of the right lung. The cardiovascular system was normal except for a soft apical murmur and no other abnormality was found.

Operative findings.—On April 21st the patient was admitted for operation, and frozen section from a piece of the tumour showed infiltration of the breast tissue by a small round-celled growth and much inflammatory change. Radical amputation was performed and the patient ultimately made a satisfactory recovery although this was delayed by massive collapse of the left lung with marked cardiac displacement.

During her convalescence a blood film was examined on the advice of the pathologist and this showed no abnormality, polymorphonuclear leucocytes being present in normal numbers.

The full pathological report on the left breast confirmed and amplified that on the frozen section (Fig. 1). The breast measured 8 in. × 6 in. × 2 in. and the nipple was not retracted. A tumour occupied the upper part throughout its whole thickness, extending from the nipple to the margin of the breast in all directions. This tumour was firm, smooth and not encapsulated. A slice taken for section appeared to consist of solid growth without demarcation. Microscopically large areas of the breast tissue were infiltrated with densely packed mononuclear cells invading the lymphatics and growing in sheets along the planes of the connective tissue. The appearances suggested sarcoma, in view of the fact that many of the cells had oval nuclei and areas of unchanged breast alveoli were present (Fig. 2). On examining the axillary tissues six glands were found the largest being 1½ in. × 1 in. × 1 in. This showed lymphatic infiltration at one end by small round mononuclear cells (Fig. 3). Projection of this part of the gland showed the average size of the infiltrating cells to be 8.8 μ , while that of the lymphocytes in the normal glandular tissue was 3.6 μ . These measurements are naturally smaller than would be found in fresh unfixed tissue.

SECOND ADMISSION

Four months after her discharge the patient returned complaining of pain in the right breast and a swelling which she had noticed a fortnight previously.

Clinical findings and operation.—A very tender mass 1 in. in diameter was palpable in the upper outer quadrant of the right breast and an enlarged gland was felt in the corresponding axilla. The patient was readmitted on Dec. 8th and apart from her leucocytes being pale and thin, routine pre-operative examination revealed no abnormality. The lungs were clear and showed no

of the previous collapse. Local amputation of the breast was performed under Evipan followed by gas and-oxygen.

Pathological report on right breast—The size was 6 in × 5 in × 2½ in, and firm areas of indefinite outline were irregularly distributed throughout the breast. Mid way between the inner margin and the nipple and on a level with the nipple was a circular, hard area ½ in in diameter,

FIG 1.—Left breast sliced from above downwards showing extensive growth. A = nipple. B = growth. C = axillary tail. D = normal breast tissue.

which did not appear to be encapsulated. The alveolar tissue was fairly profuse, and immediately above the nipple was a small fibro adenoma. There was a diffuse cellular infiltration in the outer part of the breast. Microscopically the hard nodule internal to the nipple consisted of an area of breast tissue infiltrated with tightly packed cells resembling large lymphocytes.

A full blood count was advised, and gave the following result: hemoglobin, 42 per cent; red cells, 2,184,000 per cmm; colour index, 1.0; white cells, 17,800 per cmm (polymorphonuclears 0.5 per cent, lymphocytes 99.5 per cent, mostly large). No other types of white cell were seen among the 200 cells counted but several normoblasts and megaloblasts were present. Projection showed the diameter of the large lymphocytes to vary between 12.3 μ and 15.7 μ.

Further progress—Two days after the operation the patient became extremely ill, with a pyrexia of 103°–104° F, rapid pulse, dyspnoea, and drowsiness. Examination showed collapse of the whole of the right lung and the left base. A leucocyte count was taken three days after the previous one and showed 20,400 cells per cmm, again nearly all being large lymphocytes. The general condition rapidly deteriorated, and twelve days after the operation her blood picture showed what proved to be a terminal leucopenia, the white cell count being 2000 (polymorphonuclears 16 per cent, lymphocytes 83 per cent, hyaline 1 per cent). The hemoglobin had fallen to 28 per cent. The bases of both lungs gradually re-expanded but the patient died three days later.

POST MORTEM FINDINGS

It was remarkable that the amount of lymphoid tissue in the whole body was extremely small. There were no enlarged glands palpable, and very few lymph nodes along the vessels. The mediastinal, aortic, and mesenteric glands were all unusually small, the largest found being ¼ in in diameter, and although the gall bladder was distended with bile and the bile passages enlarged, there were no glands causing pressure on the common duct. The spleen was dark purple in colour of firm consistence, and weighed 8½ oz. Section of this organ showed congestion and small patches of infiltration by cells resembling large lymphocytes. Films were made of the bone marrow from a piece of rib and from the lower end of the femur. The former showed a few mononuclear cells and nucleated red corpuscles and the latter showed fat only. Sections of liver and kidney showed no leukemic infiltration.

DISCUSSION

This case presented some unexpected difficulties, for although the possibility of a leukemic process

was suspected after the first operation, the examination of a blood film failed to reveal its presence. There cannot have been any considerable increase in the number of white cells in the blood at that time, and the post-operative increase in polymorphonuclear cells was sufficient to mask any change in the lymphocytes that may have been present. A complete blood count might have led to a correct diagnosis. In this connexion it is noteworthy that Parsons (1936), in recording blood changes associated with experimental mouse sarcoma, says that before formation of the tumour no large increase in the leucocyte count was found, although a few abnormal cells appeared in the blood, but with the development of the sarcoma an increase in the total leucocytes and also a reversal of the relationship between the cells occurred. Cellular changes were also seen in the liver, spleen, and bone marrow. The results suggested that a substance which stimulated the formation of certain types of leucocytes was present in the tumour.

In the case described, the second difficulty was to determine the site of the primary lesion. There was a definite hyperplasia of the axillary lymph glands, but here the lymphocytes were of normal size except in the connective tissue surrounding one end of the largest lymphatic gland, where they simulated malignant infiltration (Fig 3). The monocytes found in the breast nodule were, however, large and pleomorphic, and pale areas resembling endothelial cells surrounded by closely packed, densely staining large lymphocytes were present. If these cells originated in the axillary glands and spread to the breast by retrograde lymph flow, then they underwent further development in that tissue.

Dawson (1936) refers to localised mammary involvement in blood diseases when discussing metastatic breast tumours. She describes a case in which a

primary growth was found in the stomach and was associated with extensive lymph vessel carcinosis in both breasts without the formation of obvious metastases. The path of invasion into the breast was thought to be by retrograde lymph flow from the axilla, after blockage of the supraclavicular glands from the primary tumour.

FIG 2.—Section of breast (× 100). A = mononuclear infiltration. B = mononuclear infiltration in sheets along the connective tissue planes.

blockage of the supraclavicular glands from the primary tumour.

In the case under discussion it was curious that in the first specimen the infiltration was strictly limited to the upper part of the breast, the tumour though not encapsulated having a sharp margin (Fig 1). Even microscopically there was no lymphocytic infiltration in the lower half of the breast, nor could any excess of white cells be detected in the blood vessels. Attempts to make a differential count failed through lack of material. In the second specimen

however the infiltration was very irregularly distributed throughout the whole breast. It would appear that the mammary glands of this patient were for some reason specially favourable sites for the proliferation of mononuclear cells. There must have

FIG. 2.—Section of largest gland, showing infiltration by large mononuclear cells (A). B = normal lymphatic tissue. (x 45)

been some reason for the different distribution of the lesions on the two sides but this has not been determined.

A study of the literature shows that breast nodules are not uncommonly associated with chloroma and myelogenous leukemia but are rare with lymphatic leukemia the only really similar case being described by McWilliams and Hance (1912).

Their patient was a married woman of 33 who was found to have a tumour in the right breast which on excision showed the microscopic appearance of lymphoma. Five months later the patient returned with further nodules in the same side a mass in the other breast and enlarged axillary glands. Microscopically the nodules showed a huge number of small cells with round or oval nuclei resembling lymphocytes, and the diagnosis of lymphosarcoma was made. A blood count gave: haemoglobin, 30 per cent; red cells, 3,000,000 per cmm; white cells, 117,000 (90 per cent lymphocytes). The spleen became palpable shortly before death but there was never any enlargement of the superficial lymph nodes except in the axilla. At the post mortem examination all the blood-forming tissue showed transformation to a tissue in which the predominating cell was the mononuclear leucocyte.

Whitby and Britton (1934) mention atypical forms of chloromata which may occur in any tissue and be unassociated with green coloration. The blood picture in these cases may be of either the lymphatic or myeloid type.

Frevithick (1903) describes a case of chloroma in a girl of 13 with bilateral enlargement of cervical and axillary glands and bluish firm globular tumours in both breasts. Later multiple bony swellings appeared. No blood count was taken but a film revealed a leucocytosis which before death showed a rapid and large increase in mononuclear cells. Post mortem examination showed multiple deposits of green material with the microscopic appearance of normal tissue invaded by densely packed mononuclear leucocytes. A rather similar case is described by Simon (1912) in a girl of 16 who had a four weeks history of a rapidly growing tumour in the breast attached to the skin. Radical amputation was performed and the tumour found to be a chloroma. Subsequent blood counts showed a progressive

anaemia, eosinophilia and many myeloblasts. At the time of operation there was no lymphatic enlargement except in the axillary glands of the affected side but there were generalised metastases before death. Post-mortem examination was not allowed.

Ziegler (1911) describes a pseudo leukaemic mammary granuloma, and mentions that deposits stimulating growth may occur in any organ in cases of myelogenous or lymphatic leukemia.

In conclusion the experience gained by the case described suggests that it would be worth while to make a complete blood examination in any patient under 40 who presents herself with a breast tumour simulating malignancy.

SUMMARY

(1) A case of lymphatic leukemia is described in which the only gross manifestations were in the breasts. (2) The tumour removed from the left breast had a pathological appearance simulating sarcoma, with dense infiltration by large mononuclear cells. (3) Five months later a similar tumour was removed from the right breast. (4) At the time of the first operation the blood film showed no abnormality but after the second operation 99.5 per cent of the white cells were lymphocytes. (5) The post mortem findings were remarkable in that there was extremely little lymphoid tissue present in the body.

My thanks are due to Miss F. Syk, the surgeon in charge of the case for her permission to publish these notes.

REACTIVATION OF A TUBERCULOUS FOCUS BY MICRO-ORGANISMS OTHER THAN THE TUBERCLE BACILLUS

By W. PAOEL, M.D. Berlin

(From the Sims Woodhead Memorial Laboratory Papworth Village Settlement Cambridge)

REACTIVATION of a tuberculous focus usually follows its liquefaction. The old view that this liquefaction was caused by a mixed infection, especially with staphylococci, streptococci and pneumococci has been almost entirely abandoned. The view was chiefly based on the observation of mixed infection in foci already liquefied—particularly in cavities. This is clear from the careful histological investigations of Sata (1899). The same has been pointed out recently by Kasper (1932) and Roulet (1936). But exact histological or bacteriological evidence of the liquefaction of a solid focus by these micro-organisms has never been brought forward.

The clinical significance of liquefaction is the phenomenon leading to active tuberculosis (Lange 1931, 1932; Long 1933) may justify the report of a case in which there was clear evidence that micro-organisms other than the tubercle bacillus caused liquefaction of a tuberculous focus even if such an event is exceptional.

CASE REPORT

A male child, aged 4, from March 1933 to the end of April 1934, tubercle bacilli were consistently found in the sputum. From then until his death in December 1934, the sputum was negative. In March 1935 the

sedimentation rate (Westergren, 1 hour) was 17, in October it was 4. At the end of November lobar pneumonia of the right lower lobe developed, and he died from heart failure on Dec 3rd, 1936

A series of skiagrams taken between December, 1933, and November, 1936, showed disappearance of a cavity in the right upper lobe and shrinking of areas of infiltration in both upper lobes with formation of typical sharply defined "round foci." In addition small calcified nodules were scattered over the right lung

Post mortem examination.—Lobar pneumonia of the right lower lobe (grey hepatisation) with exudative pleurisy. Multiple encapsulated tuberculous round foci. In the right lower lobe in the centre of the pneumonic tissue there was one encapsulated caseous round focus the size of a small cherry, a small bronchus filled with purulent exudate was seen to enter the caseous focus, which was liquefied so that only half of its original volume remained as caseous material, the other half forming a small cavity (Fig 1). Macroscopically it looked like a partially liquefied tuberculous focus. Histological examination confirmed this impression. It was a typical partially liquefied caseous round focus with a fibrotic capsule. A purulent exudate consisting of leucocytes with very numerous pneumococci covered the wall of the cavity and seemed to invade the caseous focus which, in its marginal parts, was being destroyed by the exudate and the pneumococci (Fig 2). There were only a small number of tubercle bacilli in the centre and margins of the focus and in the leucocytic exudate invading the focus

COMMENT

The above case shows the gradual healing by encapsulation of multiple tuberculous round areas of infiltration watched for three years. Death was due to a pneumococcal lobar pneumonia unrelated to the tuberculous process

One of the encapsulated caseous round foci in the centre of the pneumonic lobe was partially liquefied.

FIG 1.—Histological appearance of the focus ($\times 7$). B = bronchus C = small cavity F = liquefied parts of the caseous focus

Macroscopically this looked like tuberculous liquefaction and therefore it was suspected that the pneumonic process was perhaps due to aspiration of liquefied caseous material and therefore a caseous rather than a pneumococcal pneumonia. Histological examination,

however, clearly showed that it was a non tuberculous pneumonia, and that even the liquefaction of the focus was not tuberculous in origin, that is, not due to an increase of tubercle bacilli within the focus

The small number of tubercle bacilli seen in the focus were apparently set free from the caseous material by its liquefaction. Moreover, there were no tubercle bacilli in the cavity produced by the partial liquefaction of the focus and in the purulent exudate of the bronchus entering the focus at one end, whereas innumerable pneumococci were found in these places. In tuberculous liquefaction, enormous numbers of tubercle bacilli are found. The small number of

tubercle bacilli set free by the liquefaction of the focus shows that the presence of large numbers of tubercle bacilli in tuberculous liquefaction cannot merely be due to liberation of the bacilli by the liquefaction of the solid parts, which make it impossible to detect them. There is ample histological

FIG 2.—Marginal parts of the focus (Microscope 1000 enlarged $\times 2$). Leucocytic infiltration rich in pneumococci

proof that in this case the liquefaction of the caseous focus was due to its invasion by a leucocytic exudate rich in pneumococci, it was therefore the result of pneumococcal infection—a non specific inflammation

I can find no report of a similar case. Carl Weigert 50 years ago said that flaring up and generalisation of a tuberculous process following measles are not caused by weakening of the general resistance or by an alteration in the response of the organism to the tubercle bacillus due to the intercurrent diseases, but a non specific inflammatory process in the lungs may involve the capsule of a caseous lymphatic gland, invade the latter and thereby liberate the tubercle bacilli enclosed in the caseous focus. The anatomical and histological findings of such an invasion of tuberculous foci by non specific inflammatory processes have, however, hitherto not been described. More recently Bézançon, Delarue, and Vallet-Bellot mentioned that if an inflammatory process of sufficient activity occurs, an old lipiodol deposit trapped in the lung may be suddenly liberated and thus disappear, but these authors also do not provide anatomical evidence

The value of the case described above does not therefore lie only in the evidence of liquefaction of a tuberculous focus due to micro organisms other than the tubercle bacillus, but also in that it shows how quiescent foci may flare up after pneumonia. This is certainly one way in which active tuberculosis may follow a non specific inflammation of the lungs

SUMMARY

A case is described in which one of the tuberculous round areas of infiltration was found partially liquefied in the centre of a lobar pneumonia. Histological evidence showed this liquefaction to be due to an invasion of pneumococci into the caseous focus. Liquefaction and reactivation of a tuberculous focus can therefore be due to micro organisms other than the tubercle bacillus

CLINICAL AND LABORATORY NOTES

CONTINUOUS VENOUS HUM IN
BILHARZIAL CIRRHOSIS OF THE LIVER

By M. R. KENAWY M.D. Cairo

REGISTRAR TO THE MEDICAL UNIT OF KASS EL-AINI HOSPITAL,
CAIRO UNIVERSITY EGYPT

Cirrhosis of the liver is endemic in Egypt among the cultivator class. It is caused by infestation with bilharzia ova usually of the mansoni type and their deposition in the liver. In the last two years I have been able to collect 6 cases of bilharzial cirrhosis with or without splenomegaly in which a continuous venous hum could be easily heard over a localised area over the xiphoid process. The murmur has the following characters: (a) it is a continuous hum which increases in loudness during inspiration and decreases during expiration; (b) it is louder in the sitting or standing position than while the patient is recumbent; (c) it is localised and not propagated and not heard at the back; and (d) it is not associated with any cardiovascular abnormality. As there has been much controversy about the source of such a hum I thought the following record might be helpful.

A male aged 20 was admitted to hospital on July 20th 1936 complaining of an abdominal swelling for a year. He gave a history of diarrhoea and terminal hæmaturia two years before. He was pale and was stunted in growth. The abdomen looked distended; the liver was enlarged three fingers breadth in the mammary line and hard in consistence. The spleen was enlarged down to left iliac fossa. Nothing abnormal was detected in heart or lungs and there was no free fluid in the abdominal cavity. Over the xiphoid process a continuous venous hum with the characters described above could be heard. The stools contained *Bilharzia mansoni* ova. The urine contained albumin and blood. Renal function normal. Wassermann reaction negative. A blood count showed: hæmoglobin 50 per cent. red cells 3,800,000 and white cells 3,200 (polymorphs 75 per cent. lymphocytes 25 per cent.). Blood pressure 100/65. Sigmoidoscopic examination showed a slight granularity of the mucous membrane and nothing else abnormal. The patient was treated with iron and a full course of tartar emetic. On Sept. 23rd splenectomy was performed. Immediately after the operation and on the following days the hum had disappeared. He was discharged on Oct. 18th.

From my experience in the other 5 cases there is no relationship between the hum and the presence of ascites nor had specific treatment with antimony (tartar emetic) any effect on the hum. The degree of anaemia and its further improvement under treatment also had no effect.

In the case recorded above the hum disappeared entirely after splenectomy. This suggests that during the removal of the spleen the source of the hum was also removed. Since the hum occurs in cases of cirrhosis of the liver without splenomegaly it could not be assumed that the spleen was the actual source and most probably it arose in some venous communication which was severed during the operative manipulations. The increased loudness of the murmur during

inspiration and its greater loudness in the standing or sitting position where the action of the diaphragm is more free and thus allows a greater rise of intra-abdominal pressure afford further corroborative evidence. Its disappearance after splenectomy as well as its complete absence on auscultation of the back excludes the possibility of stenosis of the vena cava by a perivenous hepatic fibrosis such as Dr J. L. Bates suggested in THE LANCET of May 6th (p. 1108).

CONCLUSIONS

- (1) The continuous venous hum previously recorded in Hanot's cirrhosis and Banti's disease also occurs in endemic (bilharzial) cirrhosis of the liver in Egypt with or without splenomegaly.
- (2) Six cases have been collected in the last two years. In one of them the hum disappeared after splenectomy.
- (3) Its disappearance was probably due to removal of some venous communication during the operation.

My thanks are due to Prof. H. B. Davy for kind advice and encouragement.

LYMPHATIC CYST OF THE EAR

By MR. S. S. SING M.B. Calcutta M.R.C.P. Lond.
CAPTAIN INDIAN MEDICAL SERVICE BURMA

I HAVE not been able to find any published account of the condition described in this note which I have named lymphatic cyst of the ear. I believe however that it is not uncommon.

Clinical features.—A painless tense and cystic swelling translucent on illumination appears in the concha on the lateral aspect of one or both ears. Its progress is extremely slow and it may not be noticed for a long time. When well developed it may completely fill the concha (see Figure). The pinna is not thickened and the auricular glands are not enlarged. The six patients I have seen have all been adult males living in Burma.

Pathology.—There is no evidence of leprosy or filariasis. On aspiration of the cyst a thick straw-coloured fluid is obtained. Dr N. Hamilton Lawler who was kind enough to examine the fluid from one of them reported that it contained no micro-organisms or cells and expressed the opinion that it was from a simple cyst. Evidently there is lymphatic obstruction of some sort and it is noteworthy that 5 of the 6 patients wore spectacles with curved aural supports which pressed against the angle formed by the ear and the skull. The spectacles had been worn for periods varying from 2 to 27 years. The sixth patient had no spectacles but wore a Burmese headdress called *gaungbaung* which consists of a fine silk scarf worn tightly round the head along a line passing across the forehead just above the ears and downwards and backwards over the occiput. All these patients had seborrhoea and often the irritation of the aural supports produced crop of acne and it is probable that the ear itself was irritated by the aural supports and the consequent interference with the lymphatic drainage of the ear resulting in

(Continued from previous page)

intermittent obstruction and cyst formation in the area drained, and the repeated subminimal infections may also have favoured the onset and progress of the cysts. The Wassermann reaction was done in 2 cases and found to be negative.

Treatment—The pressure behind the ear must be relieved and spectacles changed and fitted properly. The local treatment consists in evacuating the cyst through a medium sized hypodermic needle and injecting a sclerosing solution through the same needle. The cyst is emptied by applying pressure from the periphery towards the needle. The presence of blood indicates that too much pressure has been applied. Quinine urethane solution (Parke, Davis and Co.) was used but other sclerosing fluids would serve. Pressure is applied for a few minutes, and a pressure bandage could be applied for a few hours if blood appeared during the evacuation. The condition may recur but can be treated in the same way again if need be. My six patients have had no recurrence in the 2-7 years that have elapsed since the last treatment.

SUMMARY

A cystic swelling developed in the concha of the ears of 5 persons who wore spectacles with curved aural supports. A similar condition developed in a patient who had pressure of a different kind applied round his head. The cyst is believed to be the result of lymphatic obstruction. Treatment by evacuation and injection of sclerosing fluid gives good cosmetic results.

A CASE OF NÆVOID AMENTIA

BY RALPH BATES, F.R.C.S. Eng., D.P.M.

MEDICAL OFFICER, STOKES PARK COLONY, STAPLETON, BRISTOL.

NÆVOID amentia is rare enough to justify the short description of a characteristic case. Tredgold¹ summarises the syndrome as a combination of nævoid growths of the skin and meninges, mental defect

FIG 1—Photograph showing extent of the nævus

(usually idiocy or imbecility), hemiplegia, and epileptic form fits. The frequency of the condition is given as about 1 in 800 mental defectives, but the case described below is the only one discovered in an examination of more than 2000 defectives. Vascular nævi are discussed in greatest detail in the standard textbooks on skin diseases, but these do not usually mention the syndrome nor do they call attention to the association

between vascular nævi of the skin and vascular abnormalities in the meninges.

A feeble minded woman aged 36, has been under observation at Stoke Park Colony for the past five years. As Fig. 1 shows, there is an extensive nævus of the right

side of the face limited below by the lip margin and a line from the angle of the mouth to the malar bone. Above the orbit, the nævus extends to the hair margin of the forehead and on to the hair bearing area of the temporal region. There is no extension across the middle line of the face or scalp and the cartilaginous portion of the nose is not involved. On the buccal aspect the

FIG 2.—Radiogram of skull showing calcification in frontal region

nævus covers the right cheek and extends on to the palate, but is again limited by the midline.

The lower limit of the nævus corresponds with the lower limit of the embryological maxillary process. The area covered by the nævus corresponds to that part of the face which is formed by the maxillary, lateral nasal, and median nasal processes, while the nasal part of the fronto-nasal process is normal. The exception to an otherwise exact correlation is the fact that the ala nasi (which is formed from the lateral nasal process) is covered with normal skin. The islands of nævoid tissue below the main nævus are good examples of Virchow's "fissural angiomata" situated at the junction of maxillary and mandibular processes.

The conjunctival vessels of the right eye are dilated and tortuous. Examination of the left fundus shows a normal disc with rather full veins. The right fundus shows a very deep physiological cup (—7D) with the fundus raised around it. The vessels at the cup edge can be focused with —3D and those in the periphery with —1.5D. The veins are very tortuous and dilated but diminished in number compared to the left side and the arteries are small.

Examination of the limbs shows a difference in development on the two sides. The left hand is smaller than the right and the left upper limb is shorter by 1½ in. The left lower limb is an inch shorter than the right. Both upper and lower limbs show muscular weakness and increased tendon reflexes on the left side. There is slight rigidity of the left lower limb, but the plantar reflex gives a flexor response. There is no alteration in sensation.

An X-ray photograph of the skull (Fig. 2) shows irregular areas of calcification in the frontal region compatible with calcification in a plexiform angioma.

This patient has suffered from epileptic fits since coming under observation. Before the attack she complains of "pins and needles" in the left upper limb, and sometimes that the left upper and lower limbs "feel stiff". On regaining consciousness she feels "as if she has no strength" and the left upper and lower limbs "feel stiff" for a short time. Under ordinary epileptic treatment major fits now occur about once in six months.

My thanks are due to Dr R. J. A. Berry, director of medical services at the Stoke Park Colony, for permission to publish this case.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SUBSECTION OF PROCTOLOGY

At the meeting of this subsection on May 10th under the presidency of Mr G. GORDON TAYLOR, a discussion on the incidence and treatment of

Diseases of the Colon

was opened by Sir EDWARD SPRIGGS (Ruthin). Much, he said, had been written and stated about the colon in recent years and a good deal had been done to it there were those who would soothe those who would stimulate and those who would bind loosen or denervate. It had been abused for its sins and pitied for its sorrows. The condition of the colon had a profound effect on the body. It shared with the gullet and with the stomach (not with the small intestine) proneness to disease.

In a classification of over 8000 consecutive cases at Ruthin Castle, of all kinds of disease, it was found that one-third suffered from vascular disorders which were prevalent in middle age and beyond. The group of alimentary diseases including rectum liver and pancreas totalled nearly half the 8000. There were 1574 persons who had some affection of the colon including colitis diverticulosis diverticulitis, and carcinoma. The diverticulosis cases numbered 612 in two or three hundred of these diverticula were associated with other complaints. There were 51 cases of ulcerative colitis 33 of dysentery and 64 of growth excluding growths of the rectum. There were 28 cases of obstruction 8 of volvulus 142 of redundant sigmoid. Also 1620 patients had simple delay—i.e. longer than 72 hours. These were not included in the 1574 cases under review nor were cases of ptosis of the colon of which there were 304. The average age for dropped colon was 43 for colitis 44 for colon delay 47 for diverticulosis 58 and for the later stages of diverticulitis 62, which was also the average age for cancer. There were three cases of colitis in women to each one in men while the sexes, surprisingly enough, were equal as regards colonic delay. Of diverticulosis cases there were two males to each female while for diverticulitis the proportion was nine to one. Among patients with new growths males predominated in the proportion of three to one. Cases of colon disease were still mixed* said Sir Edmund because the simple precaution of examining the rectum was omitted examination of the faeces and the use of the sigmoidoscope were of the utmost value. He deprecated the growing habit of attempting a radiological diagnosis by means of a barium enema alone. Flatulence was a term used often in medical reports without a definition it might mean that a patient was bringing up wind from the stomach or was trying to do so or removing wind from the bowel or trying to do so or that he had distension or thought he had. Aerophagy was too often diagnosed nowadays. A patient with hypertrophic gastritis might retch bark and belch as long as the barium was in contact with the hypertrophic area. The effect of a small degree of distension of the small intestine was much greater than that of the same amount of distension in the large gut.

Of 1000 cases in which the patients were said to be constipated 10 per cent did not show radiological evidence of delay. In 1000 cases of real delay shown radiologically the seat was the rectum in 11 per cent

the sigmoid and rectum in 33 per cent. A fourth of the patients were unaware of delay and of these nine out of ten had no disorder referable to the colon. Failure was due to over drying of the faeces or loss of stimulus or a lesion of the anus or rectum. A purge emptied two or three days faeces therefore aperients should not be given more often than this. Of stimuli to the colon distal ones were best. The main use of paraffin was to prevent the stool becoming hard. A deserts spoonful night and morning was usually enough too much caused gurgling and discomfort. It was not normal for the caecum to be a co-spool but it could be made one. He believed that mucous colitis was now less common than formerly and some credit for that could properly be taken by doctors for better teaching about purgatives.

Were redundant sigmoid loops congenital or acquired? Or were they in part congenital and in that case did they develop as ago advanced? X rays showed that when the bowel relaxed it became both longer and wider. If it did not do so and this failure occurred many times the elongation of loops could be explained. His view was that they developed during life but twenty years observation was needed to establish that idea. In his series redundant sigmoid was commoner in people over fifty than under thirty. If surgery was contemplated it should be ascertained whether or not the bowel shortened after evacuation. If it did the case was less suitable for surgery. In cases of constipation sympathectomy had not been very helpful though it was so in Hirschsprung's disease.

Twenty per cent. of patients with ulcerative colitis still died from it. Among the advances in his own time were the giving of these patients a less restricted diet. Secondly gentle douching was a great help but not more often than on alternate days. Rectal lesions must be dealt with and a patient search made for entamoeba in five cases that organism was found only after months or years. He had usually found bacteriological methods disappointing but some physicians reported good result from sera. Dr J. R. Bell used Sir Arthur Hurst's method carefully and obtained 60 per cent of recoveries in 64 cases working in Australia where however dysentery was commoner and the serum (originally prepared by Penfold and Patterson) was more embracing than that used in this country. If the patient had not had dysentery he was being given a non-specific protein therapy. But when 20 per cent of people died and when some remarkable recoveries were recorded by another method of treatment which yet had a mortality of 20 per cent it did not follow that they were the same 20 per cent and he asked whether a patient would have recovered if he had had serum therapy. Many probably a greater number had been treated with Dr Bargan's diploccocal serum made from the patient's own organism. After the diploccocal appointment of fair hopes the reaction might tend to go too far and one American physician of wide experience said he had abandoned all method except rest and the usual symptomatic treatment not even using the douche. Sir Edmund thought that douching helped and he had seen recurrences when it had been omitted. Ulcerative colitis was a recurrent disease in a way similar to gastric ulcer and liver disease but because that liver was not usually recognized. The physician could only in brain gain the resting avoiding strain and stress and eating simple food. He had seen recurrences associated with a

period of stress and worry, with drinking beer, which was known to disagree, with colds, with pregnancy, and with other strains

In 5116 examinations there were 11 per cent of cases of diverticulosis, a term applied when pouches were present but did not cause inflammation of the bowel wall, the term diverticulitis being reserved for the stage at which inflammation and induration of the bowel wall had occurred. The distinction was of clinical importance, especially as many lay people now knew that diverticulitis could be a serious disease, and might prove fatal. His own view was that "sac" was a better term than "diverticulum". In 1920 Mr Marxer at Ruthin Castle discovered a "prediverticular" stage, and that stage had now been observed in 132 patients. Its distribution and characteristics suggested an inflammatory rather than a mechanical origin. In the present series of cases the incidence of diverticulitis was 120 out of 612 cases (20 per cent). Instantaneous photographs of diverticula contracting showed that the element of emptying was the important one, hence it was the muscular wall of the bowel which should be kept in good state so as to prevent diverticulitis. A not uncommon form was that in which mucosal folds occurred, it was this kind which was most likely to cause acute obstruction, sometimes it proceeded to definite polyposis. Almost 20 per cent of cases of diverticulitis showed some form of polyposis. The treatment he recommended consisted of giving paraffin, using a douche every 2-7 days according to the condition, avoiding rich foods and especially alcohol, and enjoining a hygienic life. Great fatigue or worry sufficed to cause the disease again to raise its head. Massage to that part of the abdomen must be avoided, he had seen real harm follow it. Purges were better avoided as a rule. Excision could be carried out in an occasional case—i.e., if the patient was well enough for the operation and the affected area was localised. It was well known that a pouch might burst and cause general peritonitis. Diverticula might also perforate into the connective tissue, Mr Marxer had demonstrated 5 such cases in a series of 120 cases of diverticulitis. Later stages accompanied by abscesses constituted grave surgical risks. If a diverticulosis was recognised soon enough and treated many of these sequelae could be prevented.

Referring next to new growths, which his colleague Dr Patterson had classified, Sir Edmund said the average age of patients with growths was 62 (the youngest being 39, the oldest 92), and the chief age range was 50 to 70. They were three times commoner in men than in women and half of them were in the sigmoid. He was surprised that diverticulitis so seldom led to cancer, bearing in mind the prevailing view of the association of cancer with chronic irritation. In this, as in so many conditions, treatment of the growth with success depended on its early recognition. In his series the length of the history varied from a week to three years. The average time from the first symptom to examination was 11 months. If discovered at a suitable stage there was no region in the body in which excision of cancer was more successful than in the colon. A more general recognition of its early stages would mean a distinct step forward in its treatment. He noted the curious ways in which cancer of the colon showed itself. Sometimes it became well established without showing a symptom, but in most cases there was a symptom which dated back a long time. Of 64 cases of growth 36 had a bowel onset—i.e., constipation, diarrhoea, or irregular motions—17 had pain, many of them a

long history of pain, 11 had a dyspeptic onset, and these were dangerous ones, because they were some times treated for months for peptic ulcer. If barium was given to examine the stomach, it should be followed right through the bowel. Eleven of the cases had rectal bleeding as a first symptom, and all those were sigmoid cases. In 7 cases no blood, mucus, or pus was detected in the faeces, showing that there was no ulceration. Every case of uncertain nature should be given a thorough examination. In all 38 cases were operated upon. In 2 nothing could be done. In most a palliative operation was performed. Excision was done in 13, and in 8 it was successful, 2 were living ten years after the operation, and one of these had had a large lump with great dilatation of the bowel behind. The features determining whether excision would succeed were the character of the growth, and whether secondaries had developed.

In conclusion Sir Edmund said that in applying scientific methods one point which emerged was the amount of suffering which could be avoided by early and adequate examination wherever there was an element of doubt. On this occasion he had been speaking of the objective signs of disease, but perhaps in no other group of disease was it so necessary to consider also the mind of the patient—an aspect of medicine which should never be forgotten.

DISCUSSION

Mr J P LOCKHART MUMMERY expressed his agreement with everything Sir Edmund Spriggs had said. He had been increasingly impressed by seeing cases of apparent ulcerative colitis which had been tested many times for entamoeba without success, but turned out eventually, after a long time, to be chronic dysentery. Whenever he suspected chronic dysentery he had emetine treatment given, in one such case the patient, a clergyman, was supposed to be dying after two months' illness, but was cured in two days and remained well to this day. He agreed that ulcerative colitis often recurred, and he attributed that fact to some hereditary disability, in some people the colon was less resistant than it was in others, and in three instances he had treated father and son for the same condition. One man had remained well ten years after treatment and when he came back with a recurrence he was found to have two very septic molar teeth. After removal of one of them he ran a temperature of 105° F, and was mentally ill. A vaccine was made from his pus, and after it had been given and the other tooth had been extracted he recovered. The speaker did not doubt that the recurrence was due to the septic teeth. Sympathectomy for chronic constipation, though a satisfactory operation, did not give permanent results. For colectomy to be justifiable a case must be a very bad one. Ulcerative colitis might be followed by a stricture extending from the caecal angle to half way to the splenic angle.

Mr ERIC CROOK asked how far constipation caused the development of redundant loops of gut. In a large mental hospital the incidence of volvulus seemed to be much greater than among ordinary people, being greater than the incidence of appendicitis. He did not know how far that was due to habitual neglect of bowel requirements.—Sir ROBERT ARMSTRONG JONES said his recollection was that at Claybury Mental Hospital volvulus was very rare, as also was appendicitis.

Dr G E VILYANDRÉ said he found it increasingly difficult, as a radiologist, to diagnose with certainty

carcinoma of either the bowel or the stomach in an early stage and he often hesitated in his verdict. He was sure it was right to employ the sigmoidoscope as an aid to diagnosis and in helping to decide whether to give a barium meal.

Mr R S CORDELL spoke of the occurrence of intussusception in cases of new growth of the colon.

The PRESIDENT agreed that sympathectomy was of relatively little value for chronic constipation in adults and adolescents. The figures showing that diverticulitis and cancer are seldom associated were confirmed by the experience of Mr Harold Edwards of King's College Hospital as set out in his Jacksonian essay. He asked whether any patient had had performative diverticulitis twice; he had not known such a case.

Sir EDMUND SPRIIGS in a brief reply said he did not know of a patient having performative diverticulitis twice. He had one series of four cases of ulcerative colitis in a family but with that exception no apparent family tendency was apparent.

SOCIETY OF MEDICAL OFFICERS OF HEALTH

A GENERAL meeting of this society was held on May 26th, Dr ERNEST WARD the president taking the chair when a discussion on the

Future of Obstetric Practice

was opened by Dr W G SAVAGE (Somerset). He said that with the present rapid fall in birth rate and in the number of potentially fertile women the value of each potential mother would be greatly enhanced. In the national interest any steps known to be the right steps should be taken to make motherhood safe to preserve potentially fit infant lives and to encourage wives not to avoid motherhood. There was however no sort of agreement as to what were the right steps in spite of much knowledge about the needs and deficiencies of nutrition during pregnancy the actual foods required and their qualities were unknown. Nor was the relation of adequate nutrition to the complications of pregnancy labour and the child's health understood.

One of the most important things to be decided was the relative spheres of the doctor and midwife and on this question there were two views which were not consonant. The British Medical Association memorandum required for every case efficient ante-natal care by or under a medical practitioner; the attendance of a midwife on every case before during and after delivery and attendance by the practitioner at the confinement whenever he or the midwife thought necessary. This scheme tended to relegate to the position of the midwife to that of a maternity nurse with midwifery qualifications acting under the medical practitioner chosen by the patient. The official and legal view recognised the midwife to be an independent practitioner capable of undertaking complete charge of a maternity case. The midwife was bound to call in a medical practitioner to her assistance in certain circumstances the speaker took the word assistance to mean that the midwife still remained in charge and the doctor's role was like that of a consultant. The scale of fees confirmed this view but he thought the majority of medical practitioners translated as set into supererogatory even if called in to some condition such as albuminuria.

not immediately connected with the confinement. The exact relation of the two professions equally entitled in law to conduct midwifery practice urgently demanded the clearest determination. The divergent points of view could be reconciled if the midwife for her part clearly understood her responsibilities and their limits and the doctor abandoned the ideas that a midwife was just a kind of nurse and that when he appeared he was entirely in charge of the case until the end of the puerperium.

Dr Savage held that the training and experience of a great many general practitioners was inadequate to fit them to act as consultants to assist midwives in emergencies except any that of illness of the child, or medical conditions of the mother. The B.M.A. suggestion that steps should be taken to increase the number of maternity cases which the general practitioner would attend did not give due consideration to two modern factors—the high proportion of cases taken by midwives (now 55 per cent. in Somerset) and the declining birth rate. The cases taken by medical practitioners in Somerset (yearly average of 1935 and 1936) were —

Doctors taking less than 3 cases a year	42
3 to 5 cases a year	62
6 to 10	46
11 to 10	31
20 to 29	14
30 or more	8
	103

Some weeks before the publication of the Maternal Mortality Report (see *Lancet* May 8th 1937, p 1125) Dr Savage had suggested as the report had done that only medical practitioners with necessary experience should be called in by midwives.

The midwife of the past and of the present in many instances was a victim of that most terrible type of education a specialised technical training built on a very limited general education. No group of people were more liable to make mistakes than one receiving such an education; hence the pattern of the rules which now harassed the midwife. The rules were being added to and the number of calls for medical assistance had increased enormously; this was unsatisfactory as it was expensive to the local supervising authority it weakened the midwife's sense of responsibility while the calling in of a doctor was not necessarily in the interests of the mother. The midwife of the future the product of the 1936 Act should be able to grasp the general principles as to what she could manage and when help was required. Dr Savage felt that the rules of the Central Midwives' Board should be simplified.

Dr ELWIS NASH (Heston and Isleworth) drew attention to the disastrous effects of puerperal morbidity from sickness of the mother and impoverishment from big medical bills. Speaking of the B.M.A. proposal that the services of a consultant should be provided when considered necessary by the practitioner he said that much depended on the word "consultant". It might be taken to mean merely the next doctor down the road. The problem of the maternity services presented many difficulties to the medical officer of health and to the general practitioner. In his district the average number of deliveries attended by doctors was 6 a year could such limited experience fit a man to be called in as an expert in emergencies? The B.M.A. was anxious to keep midwifery in the hands of the practitioner and to retain the family relationship.

which in that sphere of medicine was the strongest and deepest of a general practitioner's work, but Dr Nash felt that in view of the decline in numbers of the population the B.M.A. had left its effort until too late, and he foresaw that in time every mother would be confined in some institution. If the practitioner could be sure of his patients going to institutions and being attended by someone who was not competing with him he might be glad to be free of midwifery work. If, however, there should be a panel of local practitioners doing obstetric work and yet remaining in general practice there might be the most horrible rows until the scheme were withdrawn. The Scottish report had suggested that nutrition did not matter but the work done by Lady Williams in the Rhondda Valley seemed to demonstrate the need for consideration and investigation of this possible factor. It might be better for the individual to have at her disposal the latest scientific information and skill, with highly trained specialists working as a team, as part of a health service, on an insurance basis, but on the other hand the loss of the old relation between family doctor and patient with its profound psychological influence might be breeding a race of neurotics. Since he had written his communication to the meeting, said Dr Nash, three reports had come out, and in them mention of the general practitioner was seldom made. It was perhaps well to ponder Sir Ewen Maclean's saying that a national maternity service which excluded the general practitioner from its responsible personnel was impossible and unthinkable.

Dr J A NEILAN (Seaham Harbour) spoke from 35 years of general practitioner experience. He contrasted the opportunities of a present-day practitioner with those of thirty years ago and mentioned also that he had found modern midwives inexperienced too. To his eyes they were just flappers thinking much of their day off and keen to call in help to hurry on their cases. Dr Nash had referred to the large bills impeding some mothers' recovery, some young practitioners regrettably looked on their profession as a trade or business, although the doctor's position was a privileged one, he himself had always eliminated bills which might cause the patient or the children to suffer. There was said to be a higher proportion of abnormal cases nowadays, an idea derived perhaps from the midwives' statements on calling in practitioners in cases where no true abnormality existed. Dr Neilan thought that pelvic abnormality might be due to the wearing of high heels.

Dr AGNES NICOLL thought some difficulties would arise in the coming schemes from the fact that a woman needed to be under a doctor during her pregnancy and puerperium. She felt that the health authorities should provide general practitioner attendance. The midwives were going to be specialists in normal midwifery but they were not doctors and could not supervise the puerperium as a doctor could. Was there any reason why a woman should not have her doctor in charge of her at her own or the public health authorities' expense? She held that the general examination should be made by the general practitioner and the obstetrical antenatal examination by an obstetric specialist. It had been said that it was impossible for a practitioner to call in a local colleague as a specialist but she did not think the practitioner need necessarily lose his patients' confidence.

Dr J B HOWELL (Hammersmith) referred to the very rapid increase in use of institutional beds for

confinements in his area and to the reduction in maternity work among the doctors. In the near future sufficient accommodation would be provided to take every case. There had been a great reduction in maternal mortality in that area.

Dr CATHERINE MORRIS JONES (Gloucestershire) drew attention to the great difference between town and country practice. It would be very hard for two country practitioners in partnership to make a distinction between them and to state which of them was competent in midwifery, many country doctors had extremely good results. In Dr Jones's area delay and perineal tears were the two common abnormalities, the bulk of the midwifery practice went to the midwives who often had no afternoon off and were reluctant to take their scanty fortnight's holiday because of the difficulty of leaving their patients.

Dr NORA WATTIE spoke of the difficulty experienced in Scotland of setting up complete medical and midwifery services in six months.

The PRESIDENT wondered whether enough women would be obtainable to stay the course in the coming midwifery services.

Dr SAVAGE, in reply, thought there had been general agreement that the present position could not go on. He pictured a few obstetric consultants with the big consultants over them. That left no room for the general practitioner and he saw no need for a triple arrangement. He agreed that the calls for perineal tears had increased and doubted whether the present arrangement gave value for money. He referred to the possibility that the general practitioner might become a dodo.

NEW INVENTIONS

AN IRRIGATION CATHETER

THE catheter illustrated has been found to provide an easy and efficient means of irrigating the prostatic urethra. The procedure is as follows. After the passage of the catheter (size 16, Charrière) the rubber balloon, A, is distended with water through a separate channel to which access is given at B. The catheter

The catheter in sections

is then pulled upon gently so that the distended balloon makes contact with the bladder wall at the internal orifice. Fluid in the prostatic urethra is thus prevented from flowing into the bladder. The irrigating fluid is introduced at C, traverses the main channel of the catheter, reaches the prostatic urethra through numerous small holes at D, and is returned along the catheter to be voided at the external meatus.

The instrument has been evolved and made for me by the Genito Urinary Manufacturing Co of London.

REVIEWS AND NOTICES OF BOOKS

Fluorine Intoxication

A Clinical Hygiene Study By Dr KAJ ROHOLM
London H. K. Lewis and Co 1937 Pp 364
20s

This book contains much new and original matter. It opens with an adequate review of the known facts concerning the effects of fluorine upon health. The action of fluorides on the skin are first described and then the symptoms, signs and occurrence of acute fluorine poisoning by ingestion are discussed. The frequency of poisoning by ingestion appears to be increasing: 53 cases were recorded between 1918 and 1935. Insecticides, rat poisons, disinfectants, corrosives and preservatives provide the common sources of this kind of acute fluorine poisoning: sodium fluoride (NaF), sodium fluosilicate (Na_2SiF_6) and dilute hydrofluoric acid are the compounds which are usually responsible. Accidental ingestion is the rule; suicide is rare. The symptoms of fluorine when taken by the mouth are those of an acute gastro-intestinal irritation followed by restlessness and then collapse.

On the subject of chronic poisoning Dr Roholm, after referring to some records of doubtful cases, presents an excellent account of the original work carried out in 1931-32 by Møller and Gudjonsson in a factory in Copenhagen in which erythrite ($\text{Al}_2\text{F}_6\text{ONaF}$) was cleaned and ground. Møller found that the workers suffered from a peculiar sclerotic bone affection affecting especially the vertebral column and the pelvis and the authors assumed that the affection was caused by fluorine. In 1916 Black and McKay studied a peculiar dental disease which showed as a characteristic symptom dark patches upon the enamel of the teeth (mottled teeth). This disease was found to be widespread in Colorado and elsewhere. It affected the permanent teeth only of children who had actually grown up in Colorado and the teeth were not usually deformed. Two changes were observed: irregular patches of the enamel lost their transparency and came to resemble chalk or unglazed paper; this change was evident as soon as the permanent teeth erupted. As a secondary condition these white patches became stained with a dark pigment. The degree of staining varied from yellow to black. Transverse bands of mottled enamel might be noticed occurring especially on the labial surface of incisors and canines, in areas exposed to the light. The enamel was brittle but the teeth were not otherwise especially subject to caries. Petry and later Churchill in the U.S.A. traced the source of this condition to a high fluorine content in the water. It appeared that the threshold value is about 1 mg. per litre. Cases of dental disease of this kind have been recorded all over the world, including certain parts of England.

A valuable chapter follows upon the effects of fluorine upon plants and animals. The damage to plant and animal life around superphosphate works, certain chemical factories, copper-aluminium glass and metal (blast) factories is described. After a discussion on the natural occurrence of fluorine, experimental chronic intoxication is described in great detail. The identity of the animal disease with the human appears to be established beyond question. In the second part of the book a detailed account is given of the author's special contributions to the subject. These consist of (a) a clinical study of a large number of workers (and their families) who are exposed to fluoride both in Greenland and

in the factories of Copenhagen and (b) a careful experimental investigation of the effects of fluoride intoxication in rats, pigs, calves and dogs.

This book is of interest and importance to practising doctors, medical officers of health, to industrial medical officers in any industry in which teflar and other fluorine-containing materials are used, to veterinary surgeons and to agriculturists. We hope that it will be widely read. The translation from the Danish is good though quaint expressions have crept in—e.g. we do not say that an animal has an unthrifty appearance when we mean that it is out of condition. The attention of radiologists should be drawn to the bone conditions described in this monograph. Are the bone changes resulting from chronic fluoride poisoning discoverable in any British industrial areas?

Radiothérapie gynécologique

Curie et Röntgenthérapie By R. MATHY COLNAT
Radiologiste des Hôpitaux; Médecin de la Fondation Bergonié (Centre anticancéreux de Bordeaux et du Sud-Ouest) Chef du Service central d'Electrologie des Hôpitaux du Groupe Pellegrin Le Tondu. Paris: Masson et Cie 1936 Pp 370
Fr 60

This book gives an interesting survey of recent French opinion on the treatment of gynaecological conditions by radiotherapy. The first chapter discusses the physiological basis of treatment and describes the effect on the constituent cells of ovary and uterus and the varying sensitivity of Graafian follicles, interstitial cells, normal connective tissues and neoplastic cells of fibromyoma. In assessing the effects of radiation the work of Legend on the time factor and the relative sensitivity of the malignant tissues is accepted. The author suggests seven to ten days for intracavity radium and four to eight weeks for external radiation as periods which make it possible to give a maximum dose without increasing the resistance of the tumour. The measurement of dosage is discussed in the chapter on technique which is clearly written but not up to date.

The problem still exercising the minds of experts of the use of the Röntgen (r) to express the dose received in the tissues is dismissed briefly and a list of methods is given without consideration of all the necessary factors. On the clinical side there is a short general account of the changes produced by radiation and a careful and interesting section on each type of disease that the author regards as suitable for radiation therapy. He begins with non-malignant diseases and the chapter on fibromyoma is particularly interesting. Lipiodol injection is used in making the diagnosis and allows the size and shape of the tumour to be visualized. The question of operation or radiation is discussed without bias and various methods of treatment are described. The author prefers to give daily treatment over a period of from 20 to 35 days and delivers quite a high tumour dose—2000 r. He claims that if suitable cases for radiation are selected 50 per cent are cured a figure which includes small fibromyomas complicated by haemorrhage. For menorrhagia and metrorrhagia either radium or X-rays give satisfactory results. The dose need not be high when, as happens, the patient is near the menopause. milligramme r was usually enough. X-rays but not r is recommended for infections—a point of interest to British

who seldom make use of this possible method of attack. The doses given are very small, and in young patients produce only temporary amenorrhœa. The treatment of malignant tumours is discussed at length, and the whole section provides a useful survey of possible techniques, and their results. Such a survey is badly needed for reference, and this one will certainly be welcomed, its interest would have been increased to our readers by the inclusion of results from one or two British clinics.

The final chapter is on cancer of the breast, which organ is included in France with gynaecological conditions. The problems discussed are so different from those connected with disease of the female genital organs in the pelvis that the section must stand alone. For this purpose, it is incomplete, and the mere mention of conditions such as lymphosarcoma and nœvocarcinoma of the breast is only confusing. The glancing technique of Finzi and Holfelder is not described.

The book, which is written for the surgeon and gynaecologist as well as for the radiologist, is printed in clear type and is well illustrated.

Materia Medica, Toxicology and Pharmacognosy

By WILLIAM MANSFIELD, A.M., Ph.D., Dean and Professor of Materia Medica and Toxicology, Union University, Albany College of Pharmacy, London. Henry Kimpton 1937. Pp. 707. 30s.

This book is said in the preface to be a "text and reference book on the therapeutics, toxicology, pharmacognosy, and posology of the official drugs in the United States Pharmacopœia XI and the National Formulary VI." The author is rather optimistic in hoping that it will prove of value to people of such varied experience and needs as physicians, pharmacists, and students of pharmacy, medicine, and nursing. The section of the book devoted to pharmacognosy, which fills more than two thirds of its total bulk, is mainly of interest to the pharmacist, since the medical student of to-day is not usually expected to recognise more than a very few crude drugs nor are physicians greatly interested in the ultimate origins of the preparations they use. Each crude drug is well illustrated by photographs and adequately described. The section on toxicology opens with a general discussion of poisons and of antidotes and details of individual poisons follow. This section again is unlikely to appeal to the physician for both symptoms and treatment are dealt with very briefly and without adequate indications of rationale. Some of the statements made are inaccurate as for example that atropine is a cardiac stimulant and that iodides "dissolve sclerosis" in arterio sclerosis. The book concludes with a list of drugs arranged both in order of doses and alphabetically, and a glossary of botanical terms is appended. The volume as a whole is more likely to give help to the pharmacist than to the physician, it is a valuable work of reference on pharmacognosy.

Quarterly Journal of Medicine

THE April number (Vol. VI, No. 22) contains the following papers—

TREATMENT OF ACUTE RHEUMATIC POLYARTHRITIS WITH CONCENTRATED ANTISCARLATINAL SERUM. By John Eason and Gurth Carpenter (Royal Infirmary, Edinburgh). Forty-four cases were treated, most of

them receiving no salicylates. They remained febrile longer than salicylate-treated patients, but suffered fewer relapses and recrudescences. The authors plead for further experimental use of serum in the hope that it may prove less unsatisfactory than salicylates.

THREE CASES OF IDIOPATHIC STEATORRHEA (Gey-Thaysen's Disease). By Erik Mogensen, Copenhagen. Detailed reports are given, and the relationships of this condition, cœliac disease, sprue, and pernicious anemia are discussed.

THE HÆMOPOIETIC ACTIVITY OF HUMAN LIVER. Part II. Achrestic Anæmia and Aplastic Anæmia. By John Frederick Wilkinson, Louis Klein, and Charles Amos Ashford (Manchester). Extracts prepared from the livers of four cases of achrestic anemia, two of aplastic anemia, and one of untreated pernicious anemia were tested for their content of anti-anæmic liver principle by injection into patients suffering from pernicious anemia in relapse. A typical reticulocyte response was obtained with all extracts except that from the liver of the case of pernicious anemia. This is proof that in patients dying of achrestic and aplastic anemias the liver contains normal amounts of anti-anæmic liver principle.

OBSERVATIONS ON THE SITE OF THE ANTAGONISTIC ACTION OF POSTERIOR PITUITARY EXTRACTS ON INSULIN HYPOGLYCEMIA. By Henry Cohen and Julius Libman (Liverpool). Posterior pituitary extract, given by injection in man (eleven experiments) causes an increase in the hyperglycemia that follows the ingestion of 50 g. glucose, and at the same time a diminution in the arteriovenous sugar difference—i.e., it antagonises the peripheral action of insulin. A similar peripheral antagonism, rather than a mobilisation of liver glycogen, will therefore explain the observation that posterior pituitary extract counteracts insulin hypoglycemia.

OBSERVATIONS ON SKIN SENSITIVITY IN ASTHMATICS AND CONTROL SUBJECTS. By R. S. Bruce Pearson (Guy's Hospital). Intradermal testing for skin sensitivity to one or more of four substances (horse dander, feathers, wheat, and egg white) was carried out on some hundreds of asthmatics and of control subjects. Skin sensitivity to the inhalants is fairly common among the controls, but in general the asthmatics give a higher percentage of positive reactions and a higher proportion of large reactions. Controls with past or family histories of "atopic" conditions occupy an intermediate position between the controls giving no such history and the asthmatics. Multiple sensitivity is common. Sensitivity to inhalants is greatest both in asthmatics and in controls, between the ages of 15 and 30.

SYSTEMATISED ATYPICAL AMYLOIDOSIS WITH MACROGLOSSIA. By F. Parkes Weber, Stanford Cade, A. W. Stott, and R. J. V. Pulvertaft (Westminster Hospital). One case is reported, in a woman of 48, showing enlargement of the tongue, pain in the finger tips which were hard and pinkish red, and pain in the legs resembling intermittent claudication. Microscopically, an amyloid change, with atypical staining reactions, and a nodular often eccentric distribution, was found in the walls of arteries and arterioles in tongue, finger tips, and gastrocnemius. Tongue muscle was also involved. None of the usual causes of amyloid disease was present. Ten other cases are cited from the literature.

ACHLORHYDRIA, ANEMIA, AND SUBACUTE COMBINED DEGENERATION IN PITUITARY AND GONADAL INSUFFICIENCY. By I. Snapper and J. Groen, D. Hunter, and L. J. Wits (from the Wilhelmina Gasthuis, Amsterdam, the London Hospital, and St. Bartholomew's Hospital, London). The authors describe six cases of a syndrome involving alopecia, hypogonadism, depression of metabolism, and anemia (macrocytic or microcytic) associated with proved or probable anterior pituitary lesions. Five of the patients had achlorhydria and they suggest that this is a result of the pituitary deficiency and in turn is the immediate cause of the anemia. They suggest a similar pathogenesis for the syndrome of pituitary disease, achlorhydria, and subacute combined degeneration known as pituitary pseudo tabes.

PLASMA PHOSPHATASE IN DISEASE. A Review. By Noah Morris and Olive D. Peden.

THE LANCET

LONDON SATURDAY MAY 29 1937

ROCKEFELLER BOUNTY

WITH the death of JOHN D. ROCKEFELLER at the great age of nearly 98 years an almost legendary figure has stepped quietly almost imperceptibly from the present into the past. The day will come when his life and endeavour will be written at full length for almost alone among the world's rich men he has found a lasting place in the human imagination. There was something heroic in his mould, something dramatic in the dénouement of his life which made him the very sign and epitome of his times and the last and almost tragic representative man of an age of individualism which has perhaps passed for ever. The plot of his life is briefly told. Unbounded and self-sufficing ambition, machine-like industry and efficiency, riches amassed unemotionally and perhaps ruthlessly until they surpassed the count of man. In the plenitude of power and wealth came the conviction born of a deep puritanism that what had been wrenched without mercy from the world must be returned to it with interest. The machinery of his great wealth was put in reverse and the redistribution was carried out with the same genius and unrelenting thoroughness which went to its amassing.

To medicine J. D. ROCKEFELLER has been the greatest monetary benefactor of all time not only as measured by the vast sums he expended but also by the skill and forethought with which the money was invested. He was fortunate in his choice of medical advisers or perhaps it would be fairer to say he was incomparably skilful in choosing them. As his great wealth had been acquired with a vision which went far beyond the limits of his own country, so it was spent without consideration for national boundaries. In this country alone the Rockefeller benefactions have been of unexampled magnitude and as we look back on them we are glad to think that it would be hard to suggest how they could have been made to better advantage. Thus the schools of London, Oxford, Cambridge, Edinburgh and Bristol were given princely sums for important and overdue schemes of expansion. In London outstanding gifts were those to University College and its Hospital, to the London School of Hygiene and Tropical Medicine and towards the building of the new university premises in Bloomsbury. Many other universities and medical schools

throughout both the British Empire and the world have likewise benefited according to their needs and deserts. In the United States itself there can be few medical schools or research institutions which are not indebted to the Foundation which for some ten years or so after the war seemed never to fail to meet every really deserving demand. The central monument of the Foundation is of course the Rockefeller Institute in New York. In this institute medical research in its widest sense was given a home and endowment on a scale paralleled by no other medical research institution in existence. The finest medical brains in the world were there attracted by the facilities for research. In this institute were conducted the work of FLEXNER on meningitis, of CECIL, DOCHERTY and AVEBY on pneumonia, the brilliant researches of PEXTON ROUS on transmissible tumours, NOGUCHI's spectacular if sometimes misleading investigations on syphilis, yellow fever, and bartonella infection. Here too KARL LANDSTEINER built up the great school of immunological chemistry, the fruit of which is now only beginning to be fully borne, while even wider in interest and passing far beyond the confines of medicine was the work of ARMAND CARREL on tissue culture and of JACQUES LOEB on the dynamics of living matter. Not the least inspired of the views of the Rockefeller Foundation was the realisation that there are no real boundaries to scientific knowledge and that the problem of medical education and research is not so much one of medical education as such but of education in general. Thus as the Foundation grew in experience and wisdom it became less purely medical in its activities and in England we profited by this outlook in the benefactions to libraries and to such institutions as the London School of Economics. Relatively few of the great sums distributed by the Foundation took the form of permanent endowments. It was considered sufficient to plant the sapling and leave it to others to make the salutary effort by tending it and bringing it to fruition, but the Foundation never went by hard and fast rules and where endowment was necessary and advisable it was arranged in the most elastic way possible. No institution and no individual who benefited from the Foundation ever felt the dead hand of formal charity. It is this tact and true understanding of the very spirit of learning and research which has earned the gratitude of the medical profession and which has been a model to countless benefactors who have followed the example of the great American philanthropist. To the medical profession J. D. ROCKEFELLER will always be something more than the wizened and eccentric old gentleman who gave new dimes to pauper children—something more too than the richest man in the world whose name became as proverbial as Cæsar. For the medical world perhaps alone is in the position to realise the grandeur of the drama of restitution which was played out in his life. In the midst of the murkiness and cruelty of the arena of nineteenth-century commercialism when he stood a peerless victor he saw a vision and of that vision was born an ideal.

FOOT-AND-MOUTH DISEASE

THE task of investigating this important and damaging disease of livestock has proved to be one of exceptional difficulty. As long ago as 1924 the British Foot-and-Mouth Disease Research Committee was formed "to initiate, direct and conduct investigations into foot-and-mouth disease, either in this country or elsewhere, with a view of discovering means whereby the invasions of the disease may be rendered less harmful to agriculture." The fifth progress report¹ now published covers work carried out during the years 1930-35, and despite its high standard no dramatic solution of the problem set in the terms of reference has been reached. Needless to say, as a result of prolonged and intense study a better definition of the disease and its problems has been obtained and the presence of a standing scientific committee must have helped the Ministry of Agriculture even in carrying out with efficiency the older methods of control. The educational value of the research has been considerable, notably in the opportunities afforded to British veterinary research workers of mastering the difficult methods of virus study, the veterinary study of viruses in this country has advanced to the forefront during the last few years from a position of insignificance.

That foot-and-mouth disease may be caused by several closely allied but serologically different viruses makes the difficulty of prevention by any type of vaccine almost insuperable and the failure to work out an effective method of inoculation represents the major disappointment of the investigation. Valuable information has, however, been accumulated as to the resistance of the virus to physical and chemical influences. It has been shown, for instance, that the virus may resist cold-storage temperatures for prolonged periods and that it can be dried on fabrics and other materials and retain its virulence. These observations have led the Ministry to introduce orders compelling the cooking of animal products before feeding them to livestock and to make certain requirements as to wrapping materials. These regulations should eliminate some at least of the outbreaks. Important advances have also been made in the simplification and effectiveness of disinfection methods. Increasing reliance is now being placed both here and in Germany on alkalis, such as washing soda or dilute caustic soda, in disinfecting contaminated objects and premises. The possibility of the disease being imported into this country by birds has often been discussed, but the recent work of the committee has shown that though certain kinds of birds, such as ducks and gulls, can be experimentally infected, their susceptibility is low and they seem unable to propagate the disease by contact. Evidence that rats or other rodents take any serious part in the propagation of the disease has also been wanting. Of recent observations undoubtedly the most interesting is that hedgehogs are not only

highly susceptible to experimental infection but can also acquire the infection naturally. Not only were infected hedgehogs able to infect one another by contact but they appeared to be able to transmit the disease to a cow when placed in the same stall. Obviously much more information is desirable on the extent of infection among hedgehogs and also on the experimental course and character of the disease in these animals, but even if, as seems likely, the hedgehog is of no special importance in the natural propagation of the disease among livestock, the discovery of a highly susceptible and easily obtainable small mammal may prove to be a great help in future study. Further work has confirmed the view previously held that arthropod vectors are of little, if any, significance in the transmission of the disease.

From the purely practical standpoint it may be felt that these are meagre results to be gleaned from so prolonged and costly an investigation, but the by-products of the research have a definite value of their own. The high standard of scientific work recorded in this and previous reports on the subject makes it clear that if the practical problem of preventing foot-and-mouth disease has eluded solution it is not due to any lack of efficiency and devotion on the part of the investigators.

THE WAYWARD PEDESTRIAN

THE report of the Commissioner of Police of the Metropolis shows that, after a reduction in 1935 of the number of persons killed or injured in traffic accidents, there has been an increase in 1936 and the number killed or seriously injured has risen to 7363. The figure for pedestrians has slightly fallen, but they and pedal cyclists still make up roughly 70 per cent of the total of 57,325 killed or injured, and a special analysis of 35,851 accidents during eight months led to the assessment of 83.5 per cent in which pedestrians were regarded as to blame, another analysis for the whole year produced a figure of 76.4 per cent. Among pedestrian children there were 5459 casualties, 89.9 per cent of the total, for which they themselves were deemed responsible.

Such phrases as "to blame" and "deemed responsible" are perhaps unavoidable, but they tend to obscure the fact that modern traffic is demanding from mankind a new set of responses and reactions for which his previous experience has not prepared him. "Hesitating in traffic" accounts for 5.4 per cent of accidents to blame worthy pedestrians and is, especially for the very young and the old, a form of behaviour not likely to be eliminated even by a strict application of the law of the survival of the fittest. "It may be irritating," says Sir PHILIP GAME in his report, "to have to walk warily and to be thinking constantly of traffic when there are much more interesting things to think about", but it may be not only irritating, it may be impossible, to maintain a forced attention which, unlike the process of avoiding collision with fellow pedestrians, cannot be relegated to centres below the level of the cerebral cortex. We must, in short, be ready to

¹ Ministry of Agriculture and Fisheries. Fifth Progress Report of the Foot and Mouth Disease Research Committee. London, 1937. H.M. Stationery Office. 7s.

recognise difficulties and limitations in the demands to be made upon the conscious control of human actions in these new circumstances and to accept the need for restrictions which would not be necessary if we all could be sure of doing the right thing at the right time. There are however helping to swell the distressing totals human factors dependent not upon the inadequacy of perception and reaction but upon the positive development of harmful behaviour. The sense of power and the thrill of speed called forth by the command of a modern car become dangerous incentives whose results can be studied in newspaper reports of fatalities. On the other side exists a resentment against speed and the domination of weight and power which expresses itself in unreasonable behaviour. The objection of cyclists for example against carrying rear lights was supported by the rational argument that if rear lights were compulsory then the cyclist whose light failed was in far more danger than he is at present when the motorist is compelled to watch for the unlighted machine. Behind this objection there probably lay the unexpressed desire not to make things more easy for the motorist. It has been said that many a dead man had the right of way but the vindication of his claim has brought little of value to him or to posterity. Add to this the British characteristic whether for good or evil of a preference for independence and we can understand Sir Philip's suggestion that something might be done to check by law the most flagrant of the suicidal wanderings of pedestrians. It seems unquestionable that further measures of control are necessary. The American prohibition of crossing a road diagonally (called jay walking) might help to set up a new and safer behaviour to the advantage of all users of the road and both drivers and pedestrians are familiar with the indecision at a marked crossing called forth by the pedestrian's doubt whether an oncoming car intends to give him the right of way and the driver's irritation consequent upon his need to waver on the hesitant one. Some means might be devised of indicating automatically the intention of the driver. These and other measures call for trial but there remains an uncomfortable feeling that perhaps the greatest danger of all is of becoming reconciled to a casualty list equal to that of a rather important war.

EXPERIMENTS ON THE AETIOLOGY OF LUNG TUMOURS

SINCE the beginning of the experimental production of cancer with carcinogenic substances it has been believed that the carcinogenic effect of these substances is confined to the site of application—usually the skin. This belief is probably correct for the skin is the site at which cancer of the skin hardly ever develops outside the area treated with the carcinogen. But the production of mammary cancer in both males and females by cutaneous application of oestrogenic hormones has shown that cancer can develop at a site remote from the skin to which they are applied even

although the skin itself never responds to these hormones by carcinogenesis. This effect is not restricted to animals from a highly inbred strain with a high incidence of mammary cancer in the females as has been suggested but has been observed in animals from an inbred strain with a low incidence and in mice of mixed strains with a low incidence of mammary cancer in the females. It is seen that the oestrogenic hormones which in physical properties and in chemical constitution are closely allied to such carcinogenic substances as benzpyrene or dibenzanthracene may be absorbed by the skin without inducing a cancer locally but may have a carcinogenic action on one particular tissue remote from the site of application—the mamma—to which they travel in the blood.

These new facts have reawakened interest in the occurrence of lung tumours in mice whose skin has been painted with tar. This sequence had been noted by a number of observers beginning with MURPHY and STURM but hitherto has not been thought significant. The reasons for ignoring it were first that it is not of universal occurrence being seen most often in stocks of mice that developed lung tumours spontaneously, secondly that the spontaneous lung tumours of mice are mostly benign, and in records of growths in the lungs of mice subjected to tar painting a clear distinction has seldom been made between benign and malignant growths. To account for these tumours arising in an organ to which tar had not been directly applied it was often assumed that the tar had reached the lung by inhalation. That the inhalation of dust particles coated with tar may give rise to malignant lung tumours in mice has been demonstrated by AROYLE CAMPBELL.¹ Recently however, CLARA LAYCH² and subsequently ANDERVOORT³ have shown that subcutaneous injection into mice of dibenzanthracene dissolved inlard which is followed by development of sarcomata at the site of injection will also produce lung tumours. This effect was seen in a mixed strain of mice and in a highly inbred strain A which showed a high incidence of spontaneous lung tumours. In this latter strain the lung tumours arising after the injection of dibenzanthracene appeared more rapidly and in greater numbers than they would have done spontaneously. In seven other highly inbred strains which do not show a high incidence of spontaneous lung tumours the subcutaneous injection of dibenzanthracene did not produce lung tumours although it was followed by the appearance of what ANDERVOORT calls spontaneous tumours (presumably sarcomata) under the skin. Since P. R. PEACOCK has ingeniously demonstrated that such carcinogenic substances as dibenzanthracene when injected subcutaneously are carried away rapidly from the site of injection by the blood stream and thus reach internal organs the appearance of lung tumours after cutaneous or subcutaneous application is easily explained. But why the

¹ Campbell, J. A. (1924) *Proc. Roy. Soc. Med.* 18, 24.
² Laych, C. (1931) *Proc. Roy. Soc. Med.* 24, 21, 22, 23.
³ Andervoort, H. R. (1932) *Proc. Roy. Soc. Med.* 25, 212, 213.

carcinogenic action of these substances focused on one organ—in this case the lungs? We have to postulate a special organ susceptibility to cancer, which varies in different strains and even in different mice, and it becomes clear that there is a close similarity between the production of lung tumours by injecting dibenzanthracene and of mammary tumours by painting the skin with oestrogenic hormones. The findings of ANDERVONT greatly complicate the problem of the aetiology of lung tumours in man. For we can no longer confine our attention to carcinogenic agents capable of reaching the lungs by inhalation, but must also consider the possibility of carcinogenic agents reaching the lungs by the blood stream.

In one paper ANDERVONT refers to the growths in the subcutaneous tissue and in the lungs as "subcutaneous tumours" and "lung tumours" without giving details of their benign or malignant nature, but it can be taken for granted that all the subcutaneous tumours were sarcomata. In another paper he gives illustrations of some of

these tumours, which establish their malignancy, and he describes the successful serial transmission of four lung tumours obtained in Strain A by dibenzanthracene and of one spontaneous lung tumour from a mouse of the same strain. The last-mentioned tumour was an adenocarcinoma and retained its structure in the course of propagation, but in three other growths the morphological appearance underwent a change which ANDERVONT describes as a sarcoma development, similar to that observed by M. HAALAND in 1908 in a mammary carcinoma. Among the skin tumours of mice obtained by tar-painting there have been many, composed of spindle cells and having the morphological appearance of a sarcoma, which on closer histological analysis proved to consist of cells which were derived from the epithelium but had assumed a spindle shape. It is not clear why ANDERVONT has not considered this possibility, and until it is excluded there must be some doubt whether the change he has observed really represents the development of a sarcoma in a carcinoma.

ANNOTATIONS

THE COST OF SALVAGE

RECENT questions in Parliament elicited the fact that in an average year a sum of rather over two million pounds is expended on the medical inspection and treatment of children in the public elementary schools of England and Wales, and a like sum on the education and treatment of children of the same age in special schools. In each case the expense is met in equal parts by the Exchequer and the local rates. And it was evident from the form of the questions that not everyone is satisfied of the justification for expenditure on this scale. The general work of the school medical service needs little extenuation, it is an integral part of the campaign for national fitness, less obvious to those without inside knowledge is the justification for the heavy cost of special education and treatment of the blind, the deaf, and the mentally defective. Practically speaking these defects cannot be removed, though they may be arrested, the victims cannot be made normal, and yet the cost of their treatment and education is twice or thrice as great as that of those who are of so much greater value to the community. The answer lies in the word "training," for though the defects themselves may be permanent the resulting handicaps can be so lightened that after special training for a few years the deaf can communicate with their fellows, the blind can read and write, and the mentally defective acquire stability, while the majority of each group is taught occupations which save them from being in misery themselves, a hopeless drag on the education of the normal, and a life long burden on the community. Even with the mentally defective, experience in areas like London and Birmingham shows that about half the known ex-pupils are more or less self supporting, and less than a fifth are inmates of any kind of public institution. In schools for the blind and deaf the results are better than this. The process may not be the creation of a national asset, as is the prevention and cure of disease in the more normal, but it is the liquidation of a debt. Looked at merely from the economic aspect a long view reveals the fact that a generous outlay wisely dispensed is sound financially, as in the modern legislation for the training

of the blind, wisdom and humanity go hand in hand. To ignore the existence of defectives—physically and mentally—would be foolish as well as cruel and proper provision for them is inevitable. It must be realised also that the more expensive measures often give the better results and are in the long run the least wasteful. With the higher type of defective a little more spent on treatment and training for a few years may save the expense of upkeep for a life time. The principle must be applied with discretion and, in fact, precautions are taken to prevent waste of effort in attempts to train the untrainable, the selection of suitable cases falling mainly on the medical officers. The work of prevention, cure, and salvage is admittedly incomplete, but as far as it goes it is well carried out and well worth the money.

GASTRIC ACIDITY AND CHRONIC ALCOHOLISM

ABUSE of alcohol has been for long regarded as a cause of impaired gastric secretion. Statistical data upon this point have, however, been scanty, and in recent years it has been found that increased acid secretion may be present in certain types or in certain stages of gastritis. Information on the gastric acidity of 105 alcohol addicts, all of whom had consumed large quantities of alcohol either daily or periodically over months or years, has been collected by P. M. Joffe and N. Jolliffe.¹ The alcohol test-meal was used, and if free acid was absent in the first three samples, histamine was given in addition. Of the 105 patients examined, 77 men and 28 women, achlorhydria was noted in about one third, that is, no free acid was secreted after administration of histamine. Of the remainder about half showed a gastric acidity below the average normal value, and half an approximately normal secretion. Thus incidence of achlorhydria is about three times as high as would normally be expected in a series of control subjects of the same age and sex distribution. These figures might at first sight seem to confirm the view that alcohol per se is a frequent cause of achlorhydria, but certain difficulties arise in accepting this explanation. Many of the subjects examined

¹ *Amer. J. med. Sci.* 1937, 193, 501.

suffered from complications. The authors state without giving any explanation of what seems a remarkably high incidence that 26 per cent. had pellagra and 70 per cent. polyneuritis (including 22 also having pellagra). Of those addicts not suffering from one or both of these complications only 15 per cent. were found to have achlorhydria, an incidence which is only very slightly higher than might normally be expected—i.e. 12 per cent. Amongst the polyneuritis patients 20 per cent. showed absence of free acid and amongst the pellagrins 52 per cent. The amount of alcohol consumed and the length of time it had been taken did not appear to be concerned in these differences, and nine of those with normal gastric acidity had drunk from 8 to 24 ounces of whisky daily for periods up to 40 years. The association of alcohol excess, achlorhydria and proved lack of vitamin B was somewhat striking but other workers have shown that in hereditary achlorhydria is not a frequent finding.

No relationship was found between the degree of anaemia or of liver dysfunction (as far as this could be judged and tested) and the frequency of achlorhydria and the authors suggest that some factor closely associated with vitamin B may be concerned in the prevention of achlorhydria; this they refer to as the achlorhydria preventive factor and regard as distinct from either vitamin B or the pellagra preventive fraction. It is not necessary to postulate such a factor when recognising the importance of dietetic factors in the maintenance of normal gastric secretion, thus lessening the significance of the direct effects of prolonged irritation from abuse of alcohol in reducing this secretion. If a man must drink to excess it would seem that he will better preserve his gastric acidity if he takes his wine with bran.

THE BLOOD PICTURE IN INFANCY

MacKay's classical study of the haemoglobin level in infancy published in 1931¹ has been followed by similar large scale investigations in all parts of the world. Two recent surveys, one from Gothenburg and the other from Aberdeen bring out further important facts about the cause of the so-called nutritional anaemia of infancy. Dr Nils Faxén² using well controlled technique and statistical methods of analysis studied all the red cell elements in 374 infants which he considered were in every way healthy. They all weighed at least 3000 grammes at birth; they were breast fed with the addition of vitamins until six or seven months when mixed feeding was gradually begun and they all lived at home under the care of visiting nurses from the children's care centre. All children who had had any illness were excluded. His curve for haemoglobin levels during the first year of life is considerably higher than that of other observers though he notes the same tendency to a lower level of red cells and haemoglobin and smaller cell size that has been found by all workers in the second six months. Faxén himself attributes his satisfactory figures to the careful selection of his material and his children must be regarded as healthy infants living under the best conditions. He found no lowering of haemoglobin during the winter months as others have done and believes this is explained by his exclusion of children showing any infection. The truth of this conclusion is only too obvious from different results obtained by Dr Fullerton³ working with less carefully selected

children in Aberdeen. He found subnormal haemoglobin levels in 87 per cent of 298 infants from poor homes between the age of nine and twenty-two months and he concludes that this anaemia is due mainly to iron deficiency dependent on low birth weight, artificial feeding and infective illness. The part played by even mild infections originally suggested by Josephs⁴ is well brought out. A group of 26 infants aged six to twenty-two months was observed for a year in an institution under excellent dietetic and hygienic conditions. The haemoglobin level was lowered with unfailing regularity after each infection however mild even pyrexia associated with teething was effective. Thus fall occurred even when iron was already being given and no response to therapy was made until several weeks after pyrexia had subsided. Why fever causes a fall in haemoglobin is unknown. Possibly the sum of unobserved and mild infection is responsible for the slight fall seen even in Faxén's admirable children. Unlike other workers, Fullerton does not regard maternal iron deficiency as likely to be a significant aetiological factor. From theoretical calculations he decides that this anaemia of infancy cannot justifiably be called "nutritional," since during the first nine months deficiency of iron intake has little effect on the haemoglobin level. On theoretical grounds alone his conclusion that the importance of a deficient iron intake in infancy can be at present only a matter of conjecture is possibly correct but the practical fact demonstrated by MacKay remains—namely that infants given iron gain weight better and resist infections better than children not given iron. Fullerton himself holds that all children should be given medicinal iron after even mild infections. Since mild infections seem inevitable under the present conditions of town life and over-crowding and the healthy babies fulfilling Faxén's ideal criteria are probably rare in this country it seems wise to attempt the widespread prophylaxis of the anaemia of infancy whatever its cause by the use of medicinal iron.

FRIENDLY GIVING

Not only do we help to support the needy by grants of money food coal and clothing but by advising them when in difficulties or ill-health by providing medical or dental attention invalid comforts and medical appliances we arrange for holidays and even for Christmas gifts through our special Fund. We recommend suitable schools for the young help with fees and outfits and advise as to future careers. We also try to reconstruct those lives which have been shattered by bereavement lack of means and ill health.

These words are quoted from the annual report of the Ladies' Guild of the Royal Medical Benevolent Fund and the detailed report of the various committees show how well and truly this work is being carried out. It is a record of personal service of which the guild may well be proud. The hon. visitors have paid more than 225 visits to beneficiaries during the year and the cases committee has dealt with 402 persons while aid and tance and supervision have been given in the education of 66 boys and girls. The clothes committee reports a successful year with 681 parcels sent to 370 beneficiaries in spite of the extra work entailed by a flood in their premises. Three new branches of the guild have been opened at Weston-super-Mare East Devon and Gray Thurrock and others are in view. But the need is very great and the work of the guild and society is always increasing since their help is not limited to any

particular district or to those who have previously subscribed to the funds. Subscriptions, donations, and gifts of clothing are therefore urgently required and should be sent to the guild at Tavistock House North, Tavistock square, London, W C 1

INJECTION TREATMENT OF HERNIA

THE treatment of hernia by injection is evidently becoming popular in the United States. Individual clinics are now able to report the results in many hundreds of cases, and it appears that, with carefully standardised technique, the fear of serious complications need no longer be deterrent. The treatment was introduced into the surgical department of the University Hospital of Minnesota in 1931, and in a recent symposium¹ A F Bratrud and F S McKinney relate their experience of no less than 700 cases of hernia treated during five years. Of these, 300 were selected for statistical study because they had had at least six injections each and had been admitted to the clinic for treatment before 1936. In the greatest number the hernia was indirect inguinal, a few were scrotal, and there were also some indirect and recurrent. In all, 83 per cent of the patients were cured. Among factors in success the fitting of the truss and the coöperation of the patient in its use rank high. At the Minnesota University Clinic the fitting of a new truss is part of the routine, it has to be worn day and night during treatment, and its use is not discontinued till six months after the last injection. The selection of a sclerosing solution has also been given very careful attention and Bratrud reports that the best results are now obtained with the solution known as Proliferol with the addition of two drops of a phenol thuya mixture to each cubic centimetre. Proliferol is a distillate of several vegetable drugs to which have been added tannic acid, benzyl alcohol and thymol in various strengths up to 1 per cent. The phenol thuya mixture contains phenol 50 parts, alcohol 25, and Lloyd's specific tincture of thuya 25. Either solution can be employed alone, or they can be injected alternately or in combination. C O Rice of the Minneapolis General Hospital reports favourably on a mild soap solution, which causes less pain and requires no preliminary injection of a local anaesthetic. He claims cures in 379 patients with 445 hernias, no case being pronounced cured until there has been no impulse for six months after the last treatment and until the patient has been without his truss for at least four months. Another preparation used is sodium psyllate, sold under the trade name of Sylnasol, it is a solution of low viscosity that spreads through fascial planes over a wide area.

Martin Biederman² of New York classifies the causes of failure under three headings—unsuitability of the truss, failure of coöperation, and unsuitability of the solution—and he points out that all three factors are controllable. The selection of cases still presents some difficulty, especially at this stage, because the protagonists of the method naturally want to keep an eye on their statistics of results. The indirect inguinal hernia gives the best results, but the value of the method is really more apparent in cures of the much more difficult hernias and in cases where operation has repeatedly failed. Opinion seems to be divided as to whether the method is applicable to femoral hernia, and Bratrud holds that femoral and umbilical hernia should not be treated by injection unless a truss completely relieves the

symptoms. Sliding hernias and irreducible hernias are not to be treated by injection. Its use for patients in whom operation is dreaded because of respiratory or cardiovascular disease is likely perhaps to make most appeal to surgeons in this country.

Complications have been remarkably few, and the great majority of patients do not require rest in bed, even for a few days. The commonest complication seems to be swelling of the spermatic cord, and fears have been expressed about sterility, but after a special investigation C E Read decides that there is no such danger. Atrophy of the testis has not occurred in the Minnesota clinics and strangulation supervened twice only. With faulty technique the sclerosing fluid may be forced into the peritoneal cavity, and lower abdominal pain is a signal that injection should be stopped. Ordinary precautions should preclude the intravenous injection. Excessive local reaction, with sloughing and abscess-formation, does not seem to occur with the use of the solutions now recommended, but as Bratrud says, it must always be borne in mind that there is a definite technique, and that unless this is learned great harm may be done. The placing of the solution at the desired site may not be so easy as the descriptions suggest. Thus N N Crohn³ says that he experimented with injections of methylene blue in cases prepared for operation and at the first few attempts was astonished at the failure of the injected solution to be at the expected sites. With experience, however, accuracy can be assured. Crohn says that the aim of injection should not be to produce a large mass of scar tissue filling a large gap. Scar tissue is vulnerable because it is inelastic, and repair by a small amount of fibrous tissue at the right place is more likely to give permanent cure, although the larger scar may give a fallacious sense of security.

AN IMPROVED TOMOGRAPH

In thick parts of the body the interpretation of radiograms is often rendered difficult owing to the superimposition of shadows. This is especially true for the chest, where shadows arising within the lung are partly or completely masked by those cast by the bony and muscular chest wall. Since 1921 attempts have been made with increasing success to photograph a selected plane in the interior with the elimination of all other planes. This technique is now generally known as "tomography" (τεμνειν, to cut), the terms "planigraphy" and "stratigraphy" being also used. The method is based upon the principle of similar triangles. The distance from the film to the plane or stratum which it is desired to investigate is first determined. During the exposure tube and film move in opposite directions, being coupled so that their movement takes place about a pivot in the selected plane. The result is that objects in this plane are sharply outlined on the film since they are projected on to the same part of the film during the excursion of the tube and film. Objects in other planes are blurred in varying degrees up to complete extinction according to their distance from the plane selected. Thus, for example, a clear view of the pulmonary vessels can be obtained with complete elimination of the shadows of the ribs. In Grossmann's apparatus, a photograph of which was reproduced in a recent article⁴ in our own columns by McDougall, the tube moves at the upper end of a pendulum while the film moves at the lower. Twining has now ingeniously devised a much simpler

and less expensive method.⁴ This is an adaptation of the movement of the tube and of the Potter Bucky under-carriage already provided in the X ray couch in common use. Tube and under-carriage are coupled so as to provide the movement required. The tomograms published by Twining appear to us to be at least the equal of those of Grossmann. At this stage in its development the ultimate value of tomography in practice cannot be assessed. Its application must however necessarily be limited by the fact that few structures lie in one plane for any distance. Nevertheless sufficient progress has been made to establish its worth in certain situations notably the lungs where for instance it can reveal an abscess invisible in the ordinary radiogram. It also promises to be of value in certain hitherto inaccessible regions of the skull and spine despite the fact that it fails to exhibit the cancellous tissue of bone. The interpretation of tomograms will however always call for judgment and experience in a high degree.

THE MORTALITY OF JEWS

In the literature of racial susceptibilities a good deal of attention has been paid to the incidence of disease and mortality from different causes amongst the Jews. An addition to this subject matter has been made by Drs. Franz Goldmann and Georg Wolff who have published a careful study⁵ of the mortality experienced by Jews in Berlin during two periods of years 1924-26 and 1932-34.

For the earlier years population figures are available by sex and age so that death rates at ages and standardised rates can be calculated. The importance of the latter is shown by the fact that although the crude death rate of the Jewish population is about 20 per cent. higher than the rate of the total population of Berlin their standardised rate is 10 per cent. below. The Jewish population contains proportionately more persons at the two extremes of life where mortality is highest. In the latter years 1932-34 only the total populations are available so that the comparisons of the mortality of Jews and non-Jews are limited to crude rates which the authors interpret with proper caution. The death rates at ages in 1924-26 from all causes show the Jews in a very favourable position in the first few years of life holding a slight advantage from ages 17 to 40 but unfavourably placed at ages over 60. Their infant mortality rate is particularly low 40 per 1000 live births in 1932-34 compared with the figure of 61 for the total population. From infectious diseases their mortality experience is considerably more favourable than that of the non-Jewish population their advantage being particularly striking in the death rate from tuberculosis. According to the figures for 1924-26 the standardised rate of the Jews from this cause is less than half the corresponding rate of the non Jews.

The crude rates of 1932-34 also favour the Jews but to a much smaller extent. This narrowing of the difference in a short space of time between the two races suggests to the authors that the lower mortality of Jews is likely to have been due rather to more favourable economic circumstances amongst the Jews than to a greater degree of immunity peculiar to the race. From cancer they show a slightly lower death rate than the non Jew and some considerable differences in the sites mainly concerned. For instance in the

total male population 42 per cent. of the deaths were referred to the oesophagus and stomach in the Jews only 27 per cent. in the total female population 10 per cent. of the deaths were referred to the uterus in the Jews only 9 per cent. The higher death rate of the Jews from diabetes which has often been commented upon is confirmed by these figures. The standardised death rate of males exceeds the rate of all males by 42 per cent. of females by 75 per cent. On the other hand the Jewish rates at under 40 are below those of the total population. It is not until age 50 is reached that their experience becomes unfavourable and at ages over 60 the rates of both sexes are approximately double the rates of the general population of Berlin. They also show distinctly high death rates from diseases of the circulatory system and arterio-sclerosis, and a relatively unfavourable experience as regards suicide. Between 1924-26 and 1932-34 their crude death rate from suicide has increased to an appreciably greater extent than is apparent amongst the non-Jewish population.

How far these various differences can be ascribed to racial characteristics it is difficult to determine. Economic status, personal hygiene, occupations and customs may all play their parts. Goldmann and Wolff fully recognise this and plead for the further collection of data in Palestine and elsewhere to aid in the interpretation of their own excellent analysis.

EXCESSIVELY RAPID HEARTS

For the human ventricle to beat at a rate of 300 per minute seems to be very rare. Only three cases of a ventricular rate exceeding 300 have been reported and only sixteen of a rate above 280. Experimenting with animals, Lewis and others found that when the auricles of the mammalian heart were stimulated to rates higher than 300 per minute the ventricles did not respond and dropped beats or a two to one rhythm ensued. Lyon¹ reports the case of a negro infant aged 4½ weeks with acute streptococcal meningitis, in which the ventricular rate recorded electrocardiographically ten days before death was from 310 to 313 per minute. At autopsy the heart appeared normal to the naked eye and microscopically it showed no sign of infection or fibrosis. Copies of the electrocardiogram were submitted to a number of cardiologists both in America and in Europe nineteen of whom diagnosed paroxysmal auricular flutter with 1 to 1 block and intraventricular block due to myocardial fatigue. Six others agreed but could not with certainty rule out the possibility of some other diagnosis. Six others diagnosed paroxysmal ventricular tachycardia and one paroxysmal auricular tachycardia. In 12 of the 16 cases collected from the writings the outcome was a return to normal rate. In one of these a case of exophthalmic goitre the return to normal followed thyroidectomy. Of the remaining 4 the outcome in one case was not stated and 2 other patients died. Of these one who died on the third day after the onset proved at autopsy to have a widely patent foramen ovale and congestion of the cardiac vessels; in the other who died a year after the onset myocarditis dilatation and hypertrophy were found post mortem. The type of arrhythmia was diagnosed as paroxysmal auricular tachycardia in 11 of the cases, as auricular flutter in 4 and as paroxysmal ventricular tachycardia in the remaining one. It seems that in the absence of pre-existing heart disease or congenital abnormality or other grave

extracardiac disease, an excessively rapid heart beat is not in itself of serious import, but how long elapsed before normal rates were re-established in these cases, nor how long they remained normal, is not stated

GASTROSTOMY

RAPID deterioration after gastrostomy is one of the disappointments of surgery. It is all the more regrettable if the gastrostomy is part of an operation from which a cure is hoped, as for example in radical excision of the œsophagus. But even when gastrostomy is purely palliative in intent, permission to perform it has been obtained by promises to the patient that he will feel better when properly fed. Discussing the reasons for failure, E S J King¹ concludes that gastrostomy should not be attempted if the patient is in an advanced state of dehydration and malnutrition, especially in the presence of pulmonary and circulatory complications. This contra-indication does not apply to cases of sudden complete œsophageal obstruction, but to chronic cases in which the patient has gone steadily downhill. Death from infection of the wound and from peritonitis may follow the operation, and it only hastens an end already not far off. If parenteral administration of fluid does not bring distinct improvement in the general condition, gastrostomy is best avoided. The nature of the operation performed is also important. King divides all types of gastrostomy into two classes—those that result in a narrow track between the stomach and the skin surface, lined (in part at least) by granulation tissue, and those that give a track lined by gastro-intestinal mucosa. Gastrostomies of the first class are always liable to stenosis of the opening, and if the tube is left out, for reasons of comfort or because normal swallowing for a time returns, its reinsertion may be difficult. In the Janeway gastrostomy, which King has found most satisfactory, the opening is fashioned from a flap of stomach wall, cut in the transverse axis of the stomach, with its base at the greater curvature. The operation is not severe, it can be performed under local anaesthesia, and need not take longer than half an hour. The preoperative administration of fluid has already been mentioned, and King is keen about it. By far the most important consideration, however, is the choice of a suitable diet. He says, in effect, that many gastrostomy patients are suffering from severe starvation. It is necessary that the diet requirements in calories should be estimated and that the estimate should be adhered to. There is a tendency to overload the diet with fat, and to omit certain essential amino acids. Salts may be deficient, and it is not unknown for a patient fed by gastrostomy to develop scurvy or pellagra. In King's experience of 50 gastrostomies, the administration of solid food, through a grease gun, has had such obvious advantages that he strongly advocates it. The completeness of the diet is much more easily assured, the food is more readily prepared when the patient goes home, and the meals provide a degree of gastric comfort quite different from anything obtainable from a fluid diet. The importance of adding saliva and of controlling the acidity of the stomach contents are points he mentions.

THE PHYSIOLOGY OF SLEEP

ALL will recognise the fascination of the subject. Prof E D Adrian, F.R.S., chose for his John Mallet Purser lecture at Trinity College, Dublin, last week. The fact that we need to sleep—that the central

nervous system must cease work after a time—is not in itself surprising, but very remarkable is the process of falling asleep, and still more (he thinks) that of waking up again. The behaviour of different animals varies according to whether they have one rest period or several. The monophasic ringed snake rises at noon and goes to bed at 1.30 P.M., the polyphasic rabbit has 16–20 regularly spaced rest periods in the twenty-four hours. Babies are polyphasic, adults monophasic, but after the first few hours of deep sleep adults have several lighter periods. As the brain remains at rest in normal sleep it becomes more and more capable of activity, whereas the narcotised animal does not get the same refreshment. "What happens in the brain," asked Prof. Adrian, "when we cease dreaming and become our own masters again? Is there a particular region which comes into play to establish full integration, or is the half awake state due to a general low level of excitability in the cortex?" Naïve introspection suggests that there is some unifying part of the mind which is in action only when we are wide awake, and electrical methods should make it possible eventually to record the activity of different parts of the brain from moment to moment. How is this awareness brought into action when we are asleep? A loud noise in the street may not arouse us, but a child's cry at the end of the passage may make us instantly awake. Somewhere then, as Prof. Adrian put it, there must be a controlling region which decides the relative importance of the different incoming messages, and the tendency is to locate this in the diencephalon. "The induction of the sleepy state by stimulating the diencephalon shows that a change in this region can diminish the general level of nervous integration in the brain. From this it is a short step to the idea of a diencephalic centre regulating the flow of impulses to the cortex, directing attention when the brain is awake—in fact a region specially concerned with the neural activities which are essential to consciousness." He quoted Penfold as pointing out that the neurosurgeon can remove large areas from the cortex of conscious patients without their being aware of any change, whereas lesions of the diencephalon commonly involve a total loss of consciousness. The cortex judges whether the noise is important, the diencephalon, if need be, spreads the neural activity which "wakes" the sleeper. Hess, however, has shown that stimulation of the diencephalon will produce not increased vigilance but sleep. The question arises whether sleep is "a state in which the central nervous system has been reduced to a passive inactivity which tends to perpetuate itself," or whether there is not a constant activity in one region maintaining an inhibition everywhere else.

Prof. Adrian's lecture will appear in due course in the *Irish Journal of Medical Science*.

WE publish on another page an account of the evacuation of Basque children from Bilbao last week, written by the two doctors sent to Spain by the National Joint Committee for Spanish Relief. The committee, which has undertaken the care of the children in this country, may be addressed at 35, Marsham street, Westminster, London, S.W.1.

THE Minister of Health has announced the personnel of the interdepartmental committee he has set up, under the chairmanship of Mr. Norman Birkett, K.C., to inquire into the prevalence of abortion and to consider what steps can be taken to mitigate its dangers. The names are given in our Parliamentary Intelligence (p. 1313). They include two medical women and four medical men.

PUBLIC HEALTH

RAPID DETECTION OF
B TUBERCULOSIS IN MILK

By MARY L. COWAN, Maitland M.B. Toronto

(From the Department of Bacteriology and Preventive Medicine University of Manchester)

THE routine examination of milk for the presence of tubercle bacilli is done in this laboratory by biological test—i.e., inoculation of guinea pigs—or by microscopic examination or by both methods. All bulk samples of milk—i.e. mixed milk from a herd or part of a herd—are spun in 50 c.c.m. amounts for 15 minutes at 3500–4500 r.p.m. and the deposits inoculated into two guinea pigs. If the sample of milk has come from a single cow a film is made from the deposit before the remainder is inoculated into two guinea pigs. This film is stained and examined microscopically. Cowan and Maddocks (1935) found that tubercle bacilli when appearing in these films were usually associated with a particular kind of cell group. This point has been emphasised by Torrance (1927), Matthews (1931) and Davies (1933). They found it quicker easier and more efficient to examine the films for cell groups and then to examine these for tubercle bacilli.

I have attempted to increase still more the ease and efficiency of microscopic examination of milk films for tubercle bacilli. In all cases the films were examined under the low power objective ($\frac{1}{2}$ in) and if any cell groups were seen these were examined under the oil immersion objective to see whether they contained tubercle bacilli. The tuberculous cell groups are made up of pale-staining cells larger than other cells in milk and rather loosely piled up. The group may have a definite outline though this is not always true since other types of cells may overlie the large pale cells but the latter are the distinctive feature.

METHOD

Method of obtaining a deposit from milk for microscopic examination.—Milks known to contain tubercle bacilli were examined after varying treatments.

(a) Acid and alkali of various strengths were mixed with the sediment after the milk was centrifuged in an attempt to break up the deposits. It was found these did not make examination easier but rather destroyed cell groups.

(b) The milk was heated at about 60° C for about 20 minutes before centrifuging but this coagulated the cell groups and decreased the number of tubercle bacilli found.

(c) Milk was left in the ice-chest overnight and different layers spun—i.e. cream milk below cream and milk at the bottom of the bottle were spun separately. There was no regular difference in the number of tubercle bacilli in the different layers. This may have been due to mechanical difficulty of getting the layers definitely separated.

(d) Matthews (1931) reported the results of an examination of 500 samples of milk for the presence of tubercle bacilli. He spun the milk comparatively slowly for a short time and was very successful in finding the tubercle bacilli microscopically and the tubercle bacilli were associated with cell groups

such as Cowan and Maddocks found later. I therefore decided to use varying times and speeds for spinning milk known to contain tubercle bacilli and to compare the films from each. The times were 2, 5, 10 and 15 minutes at speeds of 1000, 2500 and 4000 r.p.m. I found that a film made from a deposit after spinning a milk for a short time at low speed was much easier to examine than a film from a deposit after a long rapid spin. The cell groups came down at the lower speeds and there was less other material in the films. As the deposits from different milks vary greatly in amount and consistence many samples had to be examined before deciding on the approximate time and rate of spinning to give the best average results when films were made from these deposits. This seemed to be between 2 and 5 minutes at 1000–2500 r.p.m.

Method of making films from deposits from milk.—Milk which was known to contain tubercle bacilli was centrifuged and films made from the deposit in various ways.

(a) The milk was poured off after centrifuging and the drops from the sides of the tube allowed to mix with the deposit before making the film.

(b) The milk was poured off and the centrifuge tube held inverted while films were made from the deposit allowing no milk to mix with it.

(c) A capillary pipette was used to transfer the deposit from the tube to the slide.

(d) A loop bent at a right angle was used to transfer the deposit from the tube to the slide.

(e) The deposit placed on the slide was spread with the loop.

(f) The deposit was spread on the slide with another glass slide as in making a blood film.

The films most easily and efficiently examined were those made by holding the tube with the deposit in it inverted while a loop bent at a right angle transferred the deposit to a slide (two loopfuls) this deposit then being spread with another slide. Clean new slides were used in every case.

Preparation of films for microscopical examination.—The films were allowed to dry in the air for at least half an hour and then fixed in a flame—not too hot. After cooling they were placed in alcohol and ether (equal parts) for 15 minutes and then washed with ether to get rid of the fat they were then stained in steaming carbol fuchsin for 8 min. washed in water decolorised in 3 per cent hydrochloric acid in alcohol for 3 min. washed in water decolorised in fresh acid alcohol for 3 min. washed in water counterstained with Löffler's methylene blue for 2 min. and washed well with water before drying in the air.

In staining large numbers of films simultaneously it has been found useful to put the slides into plastic slide holders and each solution into a large photographic tray with the exception of the carbol fuchsin which is put into a Staxite steel vessel to be heated over a gas ring. Each holder contains 10 slides and each tray will take 8 holders so that 80 films can be stained at one time. All the solutions can be poured back into bottles and used repeatedly.

These methods were developed by working with milk which was known to contain tubercle bacilli. I decided to try them with milk which came into the laboratory for routine examination.

Twenty-five samples of milk from single cows were spun for 3 min. at 1000 r.p.m. and also for 7 min. at 2500 r.p.m. as well as by the routine examination for 10 min. at 3500 r.p.m. The deposits after

This work has been supported and made possible by a grant from the Milk Marketing Board which is gratefully acknowledged.

spinning for 3 min at 2500 r p m gave better films on the whole than the slower spinning but the films from both these were definitely easier to examine than the films made after the routine method of spinning for 15 min at 3500 r p m. The slowest spinning was discontinued and 195 more samples of milk were examined using slow spinning and fast spinning. Of these samples 24 were found to contain tubercle bacilli by guinea-pig inoculation, 15 were found to contain tubercle bacilli by microscopic examination after slow spinning for a short time, 13 were found to contain tubercle bacilli by microscopic examination after fast spinning for a longer time.

It was thus evident that deposits from milk after spinning for 3 min at 2500 r p m were more easily examined and more frequently found to contain tubercle bacilli than deposits from milk after fast spinning for a longer time. The former was therefore adopted as a routine.

Quarter samples—Matthews (direct communication) always examined milk from each quarter separately of the udder of a cow. Thus there was no dilution of the milk containing the tubercle bacilli and so the chance of finding them microscopically was increased. I have been able to examine microscopically a very few samples of milk from each quarter of the udder as well as a mixed sample from the whole udder, but there was no doubt that the films from the "quarter samples" were more easily and quickly examined than those from a whole udder sample of the same cow.

Examination of films—In the foregoing description of a method for the microscopic examination of milk, stress has been put on "ease" as well as "efficiency," since, if the method was to be applied to routine examination of milk, which would involve a very great number of films, it was necessary to make the final examination by microscope as easy as possible. It takes slightly longer to spread a deposit with a glass slide than with a loop, but in the former case the cell groups tend to accumulate around the edges of the film so that under the microscope the edges can be examined first and, if there are no cell groups in this part, the slide does not need further attention, if they are there, they are found quickly and can be examined for tubercle bacilli.

Again, if the fat is not removed from the films before staining, much time is lost when examining the films under the microscope because there are many red stained particles which are fat and not tubercle bacilli and cause confusion.

With the fat removed and the films spread evenly so that the cell groups are more numerous at the edges, it is usually possible to examine 40 films in an hour without difficulty.

As stated above, the films are examined with a low power objective for the presence of tuberculous cell groups and only these cell groups are examined with the oil immersion lens for tubercle bacilli. The general description of these cell groups has been given but the best way of becoming familiar with them is by the study of films made from milk known to contain tubercle bacilli. When beginning to examine milk that may or may not contain tubercle bacilli, it would be of great advantage to inoculate guinea pigs with deposits from milk which show microscopically a grouping of cells about which the observer is dubious as to whether they constitute a true tuberculous cell group. By comparing the biological findings with the microscopic appearance confidence in differentiation is established. My own experience has been that, in examining quarter samples, when

tuberculous cell groups are present it is almost always possible to find tubercle bacilli in some of them.

ROUTINE MICROSCOPIC EXAMINATION OF QUARTER SAMPLES

First series—Having found a technique by which it was possible to make films from milk which could be easily and quickly examined microscopically I decided to try the efficiency of the method when used in a practical way. It was only by the keen coöperation of Mr Locke, chief veterinary officer of Manchester, that this series was possible.

When he received a report, after guinea pig inoculation, that milk from a farm supplying Manchester contained tubercle bacilli, he obtained quarter samples of milk from each cow on this farm when possible. Such samples have been examined from 36 farms, using the microscopic method described above. These are the results.

(a) On 11 farms no cow was found to give milk containing tubercle bacilli or cell groups indicating udder tuberculosis. These results have been confirmed by inoculation into guinea pigs in 6 cases. There was a history of the sale of a cow or cows from each farm since the taking of the original sample which gave a positive biological test for tubercle bacilli.

(b) From each of 2 farms milk from 1 cow was found to contain cell groups but no tubercle bacilli. It was possible to get repeat samples from one of these cows and in these tubercle bacilli were found as well as cell groups. No further sample could be obtained from the other cow but the local veterinary officer found tubercle bacilli in the milk by microscopic examination.

(c) From 21 farms 1 cow and from 2 farms 2 cows were found to give milk containing tubercle bacilli in films. These findings were confirmed by inoculation of the milk into a guinea pig or by post-mortem examination of the cow or by both methods. The cows giving milk in which tubercle bacilli were found by microscopic examination were removed from 18 of these farms, the milk from the cows remaining was found to have no tubercle bacilli as tested by guinea pig inoculation. The results of the test of the milk from 4 farms is not yet available and from 1 farm it was impossible to get a sample from the remaining cows.

Second series—Through the kind coöperation of Mr Amoss of Haslingden the milk from a second series of 26 farms was examined microscopically. In this series the milk had not been previously tested in any way.

Quarter samples were taken from each cow and examined as described above. From each of 2 farms 2 cows were found to give milk containing tubercle bacilli. In these 4 cases the milk was tested later by guinea pig inoculation and found to produce tuberculosis. Bulk samples from the remaining cows on each farm showed no tubercle bacilli when tested biologically.

Bulk samples of the milk from 16 of the other 24 farms were tested in guinea pigs and found to have no tubercle bacilli. The negative microscopic results from the milk of the other 8 farms were unfortunately not checked by guinea pig inoculation.

COMMENT

To sum up, quarter samples have been examined microscopically from approximately 950 cows and in 1 case only has the finding not been the same as the result from biological examination of the milk.

or post mortem examination of the cow. This was the case referred to above in which cell groups were found microscopically but no tubercle bacilli, although these were found by another examiner. No false positive results have so far been obtained.

Thus it would seem that the microscopic test for tubercle bacilli in milk, when it is done on quarter samples from individual cows, is very reliable. All films have been made from the milk within twelve hours after the samples were taken. This has only been possible by close cooperation between the field and laboratory workers and we do not know how successful the method would be if the milk were delayed in transit. Some samples of tuberculous milk have been kept in the ice chest for 24 hours and re-examined. The impression is that some cell groups disintegrate, but in no case has it been difficult to confirm the finding made on the fresh sample.

The value of a quick reliable method to diagnose tubercle bacilli in milk is obvious from the point of view of farmer veterinary inspector and consumer. A particularly careful clinical examination detected the infected cow in 86 per cent of cases on the 36 farms in the first series reported above. The average number detected by the usual clinical examination is probably lower and many cows with non tuberculous mastitis are mistakenly suspected. Therefore in at least 33 per cent. of farms visited for inspection the infected cow is missed, and after waiting six weeks for a report of a biological test the farm has to be visited again and more samples taken whereas it is possible to examine microscopically the milk from a whole herd in 48 hours.

The Atmosphere of Halifax

THROUGHOUT 1935 monthly records of deposited atmospheric pollution were obtained at five stations in Halifax and the results are discussed in the annual report of Dr G. C. F. Roe the medical officer of health for the borough. At the Wade-street station in the centre of the town more than twice the quantity of insoluble solids was deposited than at West View Park 1½ miles to the west. There is not such an obvious difference in the amount of soluble solids. The influence of rain in bringing down soluble solids is well shown in diagrams as is the amount of daylight which the centre of the city loses by reason of its hazy atmosphere. In 1935 there was an increase in deposit of more than 25 per cent. over 1934. This is explained partly by the greater rainfall in the former year and partly by the better trade conditions resulting in more factory smoke. Dr Roe comments on the unskilful way in which the boilers of many factories are stoked and hopes that employers will not only allow but encourage their employees to attend the classes of instruction in stoking provided by the local education authority. As regards domestic smoke the increased use of gas electricity and solid smokeless fuels does not appear to have had much effect but this may have been overshadowed by the large number of new houses built during the year. Dr Roe emphasises that if full use is to be made of smokeless appliances adequate supplies of smokeless fuel must be available at reasonable cost and the public must get rid of what he regards as an obsession—that there is nothing like a coal fire.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Capt. L. Moxon Browne to *Barham* as Fleet M.O. and as Specialist in Hygiene (on transfer of flag).
 Surg. Comdr. R. W. Higgins to *Warship* and R. W. Mowen to *Malaga* (on recomng.).
 Surg. Lt. Comdr. F. W. Gayford to *Malaga* (on recomng.).
 Lt. P. Spero to *Deronsire*. C. H. Egan to *Shropshire* and F. R. P. Williams to R. N. B. Chatham and R. M. Infirmary Deal.
 Surg. Lts. P. G. Stainton to *Enchantress*. M. G. Ross to *Pembroke* for R. M. Infirmary Deal and I. C. Macdonald to *Pembroke* for R. N. Hosp. Chatham.
 To be Surg. Lts. (D): F. B. Gamble and J. B. Knight.
 Surg. Lts. (D) G. P. Pearce to *Wildfire*. A. G. H. Hoberlein to *Deronsire*. W. L. Mountain to *Ramillies*. S. R. Wallis to *Victoria* for R. N. B. and D. N. Williamson to *Malaga*.

The following have been appointed Admiralty Surgeons and Agents: Mr R. A. M. Humphrey, Beer, East Devon; Mr G. Young of Rodars, at Contham; Mr F. Galloway of Vincent-square, S.W. 1 for London District No. 15 (Westminster, Victoria, &c.) and Mr J. A. Matheson, Lochgilphead, Argyll.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. R. Hall to *Ramillies*.
 Prob. Surg. Lt. L. F. Donnan to *Revenge*.
 Prob. Surg. Lt. J. K. Sargantson and Surg. Sub Lt. R. F. Hand to be Surg. Lts.

ROYAL ARMY MEDICAL CORPS

Capt. N. H. Lindsay retires on account of ill health receiving a gratuity.

TERRITORIAL ARMY

Capt. A. T. Ashcroft to be Maj.
 M. C. Oswald (late Off. Cadet Camb. Univ. Conigt. (Med. Unit) Sen. Div. O.T.C.) H. Mannington and G. B. Fbbage to be Lts.

Arrangements for the encampment of London District Territorial Army troops R.A.M.C. for annual training from August 1st-15th have been made as follows: 15th Gen. Hosp. at Shorncliffe; 16th Fd. Amb. 140th Fd. Amb. 8th Hygiene Coy. H.Q. and 12 Section at Currenden; 13 Section at Dilgate (prov.).

ROYAL AIR FORCE

Squadron Leader D. A. Wilson to Princess Mary's R.A.F. Hospital Halton for duty as Medical Officer.
 Flying Off. J. D. Milne to R.A.F. Station Warton Down.

Short Service Commissions as Flying Officers for three years on the active list: J. H. L. Newham (seconded for duty at the London Hospital) and P. A. Wilkins (seconded for duty at the Derbyshire Royal Infirmary).

INDIAN MEDICAL SERVICE

Capt. W. J. Shippey to be Maj.
 Lt. (on prob.) W. J. Young is retd. to the establishment.

DEATHS IN THE SERVICES

Colonel WILLIAM ALLAN MAY, C.B., late R.A.M.C. who died at Bath on May 18th in his 87th year was the son of Joseph May, R.R.C.S. Eng. of Devonport. He was educated at Tavistock Grammar School and qualified M.R.C.S. Eng. (1873) and L.R.S.A. Lond. (1874). In the latter year he entered the Army Medical Department becoming surg. major in 1896 and colonel in 1907. He retired in 1907. He served in South Africa (1900-4) as P.M.O., 8th Div. Field Force, was mentioned in dispatches, and created C.B. (Mil.). He was I.M.O. in Natal (1897-1902) in Egypt (1903-04) and for Tidewater district (1905-06). He served in the European war at home and was twice mentioned. He married in 1874 Cecilia Adele, daughter of the late Gen. G. A. A. N. Oshaffen, Colonial Commissioner, British Honduras.

FROM A MEDICAL ECONOMIST

V

THERE is an idea, often impressed upon young resident medical officers by their chiefs, that hospitals, in common with other institutions, possess a spirit. I used to believe this myself and even to imagine that I could feel the spirit of the hospital in which I served. But I am sure now that I was mistaken. The alleged spirit of the hospital was in fact the inspiration of my chief and his colleagues. I have lived long enough to see hospitals go down so that their lack of "spirit" was only too obvious and I have also seen hospitals restored by the exertions of able and single minded men.

They know all about this process in the public schools and, in consequence, exercise the greatest care in the choice of a head master. If they select the right man the school quickly becomes famous and attracts the sons of the most distinguished men of the time, but if a bad choice is made deterioration immediately occurs. There is nothing in bricks and mortar, in other words, to guarantee enthusiasm, nor is the memory of great service, unless it be supported by an active leadership, proof against human frailty.

The point is important in a world where the use of abstractions has assumed formidable shape. Schools, hospitals, towns, cities, countries—all, nowadays, are endowed with "spirits" and spoken of as if they were men and women. Books are written to investigate and analyse these modern monsters who, indeed, constitute a kind of Godhead.

The idea behind the fashion is, of course, that man in the mass differs from man the individual. This is accepted as axiomatic, is not mob psychology a fact of history? Men, according to Rousseau, become wholly different from their former selves when they are subjected to the influence of society and it is only necessary, therefore, to transform society in order to transform all its members. We have been working upon that idea for more than a century. The progress, in the best sense of that word, which was hoped for does not seem to have materialised.

The idea itself deserves scrutiny for it amounts to the assertion that an abstraction, society, is capable, over a longer or a shorter period, of effecting a kind of sexless regeneration. The individual plays no part, he is "influenced" just as the R.M.O. is supposed to be influenced by the hospital.

This remarkable process stands in the sharpest contrast to the kind of influences with which we are all familiar in our personal lives—for example, the coming of an enthusiasm or vocation, the birth of a deep friendship, or the love of woman or man. In these latter cases the person does experience a rebirth but the experience belongs exclusively to his or her own spirit and is, throughout, active and conscious.

Again "society" as Rousseau used the word is an elastic term. It may mean the State, the city, or the village. It may also mean the whole of humanity in reaction to the circumstances of nature. The constant reference to "the savage" in French Revolutionary writing conjures up a picture of man's ascent, by and through society, from the cave to the castle. Thus, on the one side, are ranged a whole world of dangers and threats of calamity and on the

other a "social organism" capable of effecting an unlimited number of transformations and transmutations, whereby danger is discounted and calamity overcome.

* * *

Students of English history are aware that the same idea underlay the philosophy of the Puritans. In that case, however, society meant the Presbyterian Body, association with which "uplifted" the unregenerate human creature to heights of spiritual strength. Nature was the enemy. So much so that Luther, who was by no means strict in his puritanism, denounced as a great heresy the idea that Nature might not be wholly vile. Nor was his opinion peculiar to himself or his age, the Stoics had said the same thing, though, again, in different language. These inheritors of Plato's philosophy, indeed, demanded, like their master, some ideal social structure by which men might be saved. From age to age philosophy concerned itself with the ascent not of man but of mankind. And the conclusion reached was always the same—namely, regeneration by abstraction, society, church, State, even war.

Nor has our own age failed to tread this hard beaten path. As was to be expected the ancient doctrine in its most modern form wears the complexion of science, but the features, nevertheless, are unmistakable. If for "society" we read "natural selection" we shall find ourselves immediately in familiar surroundings. Here, again, is the ascent of mankind, sexlessly, *en masse*, in the face of a hostile and unrelenting nature. As usual, all difficulties arising out of the character and behaviour of the individual man are swept aside. Man is vile and cannot ascend except by process of evolution.

What, in fact, does this doctrine of evolution teach? There are few things about life which are more fully substantiated than the rigidity of species. Whereas within the species almost any change can be effected by suitable mating, the species itself is a walled city. Evolution, therefore, in the sense in which Darwin and Huxley used that term can scarcely have come about as the result of mating in the ordinary acceptance. Evolutionists are apt to avoid this difficulty by retreat into geology—that is to say into Time. But the difficulty is not thus overcome. If the contention be merely that a given species has undergone morphological adaptation there is no ground of dispute, if, on the contrary, breeding across the type is suggested then more substantial evidence than geology can supply is necessary.

For what, in effect, is being said is that there are two kinds of reproduction, the ordinary kind and another in which masses and not individuals play the active part. These masses are the evolutionary vehicle and by their regenerative power the species is changed. It is true that, when Darwin wrote, the science of genetics had scarcely been born. But the doctrine of evolution is still preached like a gospel and forms, now, the basis of the thinking of millions of men and women.

These millions in consequence experience not the slightest difficulty in looking upon the abstraction society (that is to say non-ecstatic regeneration) as author and finisher and so in acknowledging their debt to it. All their ideas, even their religious ideas, are coloured by this attitude. Thus the teaching

that love alone can create and that the Creator himself is love has undergone subtle changes of emphasis. Above love it is insisted, stands justice to which love must needs make sacrifice. Justice is a social idea. Thus love is in debt to society individual creation to social creation. God the Father to God the Unknowable, that is to say to a mathematical point or to nothing at all.

This is a most convenient philosophy for the salesmen of debt and it is interesting therefore to note that it has been most actively taught and most widely believed in those periods when money lending was most rampant. The Greeks of the Athenian period were so bowed down by usury that great numbers of them had sunk into slavery. The Romans adopted the Stoic philosophy and Gibbon is of opinion that it was money lending debt which ruined and destroyed their civilisation. During the Age of Faith on the contrary money lending was forbidden every man in those centuries had his personal dignity as father and Christian. The Renaissance brought back classical learning—i.e. Greek and Roman philosophy—and soon Calvin, in Geneva, was giving his blessing to usury. Since then the march to ruin has been swift. To-day buttressed by evolution the money lender and his magic are enthroned in the heavens and upon the earth. Evolution society the State the common wealth—all these are pretty names for debt.

Social regeneration is monstrous untruth For

as has been said creation is by love by ecstasy and not otherwise. And this applies equally to all creation whether in the family in the arts or in the sciences. Again creation is by persons and occurs independently of any social structure. Social structures indeed exist by and through the creators' ecstasy—as witness the dissolution of beehives and termitaries if the queen is removed. There is no mass regeneration or reproduction and even the devices by which artificial insemination is brought about are vain if there be not what corresponds to an ecstasy of the reproductive cells. In other words as was said in a previous article the leader of his King thought creates the social organism just as the father of his love creates the family.

Unless these facts of experience are borne in mind abstract ideas are poison. The great central fact of life is the ecstasy of the individual being out of which creation proceeds. That ecstasy if it is real is always made flesh whether as offspring or as art music literature scientific discovery the doctor's office of healing or the craftsman's work. And always that process is attended by danger for the individual who nevertheless experiences great joy of it. Love in short is death and the resurrection from the dead it is the incarnation of spirit in flesh as well as the transmutation of flesh into spirit. This and this only is the ascent of man which ascent every man must make for himself by and through agencies which in time past very wise men did not hesitate to call supernatural and divine.

PANEL AND CONTRACT PRACTICE

A SOUTH AFRICAN HEALTH INSURANCE SCHEME

THE report of the Departmental Committee appointed by the South African Government to consider the introduction of national health insurance into the Union of South Africa has now been published and almost the whole of it is reprinted in the issue of the *South African Medical Journal* for April 24th.

The question has long been under consideration in the Union. As early as 1926 the South African committee of the British Medical Association passed resolutions in favour of establishing in the Union a scheme of insurance against sickness and invalidity to include all races and the dependents of the insured resting on a compulsory and contributory basis and starting in urban areas. The resolutions have been repeatedly reaffirmed and were included in the evidence submitted to the Departmental Committee by the Medical Association of South Africa (B.M.A.). The recommendations of the Association including those relating to the capitation fee were in substance accepted by the Committee and the report may therefore be taken as expressing not only the results of a thorough official investigation but also the views of the representative body of the South African medical profession. The two medical members of the Committee, though they have signed the report with their colleagues have each submitted a minority report dissenting from some of the Committee's conclusions relating to the provision of medical services in rural areas but the *South African Medical Journal* the official organ of the Medical Association of South Africa (B.M.A.) states emphatically that though the signatures of the minority reports were nominated by the Association their reports must not be taken as representing the views of the medical profession in South Africa or of any branch or division of our Association.

The report is a valuable and workmanlike document. The Committee made a careful study of what has been written on the subject they were at pains to ascertain the views of interests likely to be affected by a national health insurance scheme they visited many areas and they had early in their inquiries, the advantage of conferring with Sir Walter Kinnear who was on a holiday visit in the Union.

The Committee, like all other bodies that have attempted to draw up health insurance schemes in the Dominions, were impressed by the difficulties of providing health insurance in outlying rural areas. In South Africa the difficulties are especially formidable because of the relative scarcity of doctors. In 1931 the population of all races in the Union was 8 172 600 and the number of practising doctors was 1533 or 5305 persons per doctor as compared with 800 in Australia and 1500 in England. The Committee conclude that the time is not yet ripe for the initiation of a scheme of health insurance for our rural areas.

A SCHEME FOR THE URBAN AREA

A scheme however is formulated and recommended for applying health insurance on a compulsory and contributory basis to all employees both manual and non manual workers earning not more than £400 per annum and employed within the areas of urban local authorities and such other areas as the Government may from time to time proclaim. In the Committee's opinion the world bring within the scope of the scheme all workers resident within a radius of three miles from an insurance practitioner or surgeon. It is estimated that the number of such employees is 842 683. The insured person would be placed in eight wage groups the lowest wage being up to £36 per annum and the highest from £370 to £1000 and within each wage group the contribution and the cash benefits would be uniform. The weekly contributions payable by the

PANEL AND CONTRACT PRACTICE

A SOUTH AFRICAN HEALTH INSURANCE SCHEME

THE report of the Departmental Committee appointed by the South African Government to consider the introduction of national health insurance into the Union of South Africa has now been published and almost the whole of it is reprinted in the issue of the *South African Medical Journal* for April 24th.

The question has long been under consideration in the Union. As early as 1928 the South Africa committee of the British Medical Association passed resolutions in favour of establishing in the Union a scheme of insurance against sickness and invalidity to include all races and the dependents of the insured resting on a compulsory and contributory basis and starting in urban areas. The resolutions have been repeatedly reaffirmed and were included in the evidence submitted to the Departmental Committee by the Medical Association of South Africa (B.M.A.). The recommendations of the Association including those relating to the capitation fee were in substance accepted by the Committee and the report may therefore be taken as expressing not only the results of a thorough official investigation but also the views of the representative body of the South African medical profession. The two medical members of the Committee though they have signed the report with their colleagues have each submitted a minority report dissenting from some of the Committee's conclusions relating to the provision of medical services in rural areas but the *South African Medical Journal* the official organ of the Medical Association of South Africa (B.M.A.) states emphatically that though the signatures of the minority reports were nominated by the Association their reports must not be taken as representing the views of the medical profession in South Africa or of any branch or division of our Association.

The report is a valuable and workmanlike document. The Committee made a careful study of what has been written on the subject they were at pains to ascertain the views of interests likely to be affected by a national health insurance scheme they visited many areas and they had, early in their inquiries the advantage of conferring with Sir Walter Kinnear who was on a holiday visit in the Union.

The Committee, like all other bodies that have attempted to draw up health insurance schemes in the Dominions were impressed by the difficulties of providing health insurance in outlying rural areas. In South Africa the difficulties are especially formidable because of the relative scarcity of doctors. In 1931 the population of all races in the Union was 8 132 600 and the number of practising doctors was 1533 or 5305 persons per doctor as compared with 800 in Australia and 1500 in England. The Committee conclude that the time is not yet ripe for the initiation of a scheme of health insurance for our rural areas.

A SCHEME FOR THE URBAN AREAS

A scheme however is formulated and recommended for applying health insurance on a compulsory and contributory basis to all employees both manual and non manual workers earning not more than £400 per annum and employed within the areas of urban local authorities and such other areas as the Government may from time to time proclaim. In the Committee's opinion this would bring within the scope of the scheme all workers resident within a radius of three miles from an insurance practitioner's surgery. It is estimated that the number of such employees is 882 083. The insured persons would be placed in eight wage groups the lowest wage being up to £36 per annum and the highest from £370 to £400 and within each wage group the contributions and the cash benefits would be uniform. The weekly contributions payable by the

23325

Government, the employer, and the insured are as follows —

Wage-group	Weekly contribution					
	Total		Of which payable by—			
			Government.		Employer	Insured
	s	d	s	d	s	d
(a)	1	0	0	3	0	9
(b)	1	5	0	6	0	9
(c)	1	10	0	6	1	0
(d)	2	5	0	6	1	2
(e)	3	0	0	4	1	5
(f)	3	10	0	4	1	9
(g)	4	8	0	4	2	2
(h)	5	6	0	4	2	7

It is estimated that at the beginning of the scheme the annual contributions will amount to a total of £5,331,601, to which the employers will contribute 49.95 per cent, the insured 35.48 per cent, and the Government 14.57 per cent. Expenses of administration are estimated to amount to 10 per cent of the total contributions. The contributions of employers and employees would be collected, as in Great Britain, by means of insurance stamps affixed weekly by the employer on the insurance card of each employee.

The scheme would be administered by a central board of management consisting of an equal number of representatives of the Government, the employees, and the employers, one of the Government's representatives being a doctor, and locally by district boards consisting of representatives of the Government, employees, and employers, and of the medical profession, one of the latter being chosen by the local medical committee, to be set up in the area of each district board. Local medical committees would deal with such matters as the range of insurance medical services, the control of unnecessary prescribing and lax certification, and disputes between insurance practitioners. Disputes between practitioners and insured persons would be dealt with by a subcommittee of the district board consisting of an equal number of representatives of the board, and of persons appointed by the local medical committee, with a neutral chairman.

BENEFITS

The scheme would provide cash benefits and medical and ancillary services. The most important of the former is sickness benefit, which is the payment of weekly sums to insured persons rendered incapable of work by sickness. The sums stated vary with the wage groups of the insured persons. In the lowest group the sum stated is 4s, in the highest it is 32s. The insured person would receive also an additional payment for a dependent wife, or husband, and for each child, up to four, below 16 years of age. The additional sums also vary with the wage group in which the insured person is placed. Sickness benefit would be paid at these rates for 26 weeks, and at half rates for 52 subsequent weeks of sickness.

In providing cash allowances for dependents the scheme follows the precedent of unemployment insurance, but not health insurance, in this country. The Committee think that the difficulties of administering sickness benefit, especially those relating to certification, appear to be serious in all countries, and are likely to be exceptionally serious in South Africa, and they therefore submit an alternative scheme in which no provision for sickness benefit is made.

The scheme provides a maternity benefit, consisting

of (a) a lump sum payable on the confinement of the uninsured wife of an insured man or of an insured woman, and (b) in the case of an insured woman, weekly payments during the four weeks following confinement. The lump sum varies according to the wage group from £2 to £9, and the weekly payments from 4s to 32s, together with a supplementary allowance for an incapacitated husband and for each dependent child under 16.

Unlike most national insurance schemes, this scheme provides a funeral benefit, which is a lump sum payable on the death of an insured man, or the dependent wife of an insured man, or of the dependent child of an insured person. The amount varies according to age group from £4 to £11 for a man or a woman, and from £2 to £5 10s for a child.

MEDICAL BENEFIT

The most important, and most costly, benefit is medical benefit, which is described under three categories: ordinary, specialist, and hospital. Ordinary medical benefit includes (1) general practitioner services, excluding attendance on a confinement, and for an illness directly arising therefrom during the subsequent four weeks, and (2) the supply of drugs and of such appliances as may be included in a list to be prescribed by regulation. Specialist medical benefit includes all other medical and surgical treatment, the division between the two categories to be in accordance with regulations made after consultation with the medical profession. Hospital medical benefit consists of the payment of 9s per day for not more than thirteen weeks in a case in which a person is admitted, on his doctor's request, to a hospital or approved nursing home, or, where such accommodation cannot be obtained, is receiving full time attendance at home from a nurse. The dependents of the insured as well as the insured themselves are entitled to medical benefit.

The Committee recommend that the capitation fee should be that put forward by the Medical Association, which, however, they say is somewhat higher than they contemplated. It is 9s for persons with an income below £180 per annum, and 13s for those with incomes between £180 and £400. They also recommend, in agreement with the Association, that a sum equal to 25 per cent of the total value of the capitation fees should be provided to form a pool for the remuneration, on an attendance basis, of the specialists, and that the administration of this pool should be vested in the medical profession. It is contemplated that a contract will be entered into between the insurance authorities and the Medical Association for the provision of the general practitioner service, which will be open to all practitioners who desire to participate in the scheme, and that the insured persons will be free to choose their doctors from among such practitioners. The specialist services will be provided by a contract between the same parties on somewhat similar lines.

It is estimated that the costs of the benefits in the early stages of the scheme will be as follows —

Medical—	£
Ordinary	1 599 412
Specialist	247 022
Hospital	675 993
Maternity	369 276
Funeral	161 407
Sickness	1 338 309
Total	£4 612 321

The scheme follows that of Great Britain in many important respects—in particular the right of all doctors to take part in insurance practice, free choice

of doctor the capitation method of remunerating general practitioners and the assumption by the medical profession of important administrative functions. In the extended range of medical services provided and in the division of the insured population into wage groups with different rates of contribution and of cash benefits it is more in line with the German system. For the varying of the capitation fee according to the income of the patient there appears to be no precedent in national health insurance administration. It seems likely to give rise to considerable administrative difficulties, and the same may be said of the division of the insured population into eight wage-groups.

Though the Departmental Committee do not feel

justified in recommending any form of insurance scheme for the rural areas or the native areas they make certain proposals for improving the medical and nursing services of those areas. The measures proposed do not however appear to be precisely defined or adequate to deal with the difficulties described and seem in some degree open to the objections expressed in the minority reports of the medical members. But this is a subject on which no one unacquainted with the local conditions could venture to form a confident opinion.

The report of the Committee is being widely circulated and will doubtless be much discussed and it is not unlikely that their recommendations will be materially modified before they reach the Legislature.

SPECIAL ARTICLES

FOUR THOUSAND BASQUE CHILDREN

By RICHARD W B ELLIS M.D. M.R.C.P.

ASSISTANT PHYSICIAN FOR CHILDREN'S DISEASES, GUY'S HOSPITAL
LONDON AND

AUDREY E RUSSELL M.B.

ASSISTANT IN THE CHILD WELFARE DEPARTMENT UNIVERSITY
COLLEGE HOSPITAL, LONDON

THE shipment of children from Bilbao who arrived at Southampton on Saturday is a grim reminder of the magnitude of the refugee problem created by modern warfare. When it is realised that the ship could have been filled many times over with children whose parents would prefer to be separated from them for an indefinite time rather than let them face existing and imminent conditions in Bilbao that very many more have already been evacuated to France; and that the population of Bilbao is still nearly double its normal figure, some idea may be gained of the work of evacuation which still remains to be done. As the arrival of this group of children has already aroused interest and sympathy in this country we feel that a few particulars of existing conditions in the Basque capital and of our impressions gained of both parents and children during the medical examinations carried out there may be enlightening.

THE SITUATION IN BILBAO

On visiting the *Asistencia Social* (the ministry directly concerned with the refugee problem) and the institutions for orphans and the aged under its control it became obvious that the Basque Government is making magnificent efforts to deal with difficulties becoming daily more impossible. Most of the public services are still operating though the schools have had to be closed owing to the incessant air raids the women and children spending most of the day on the steps of the refugios (or bomb shelters) ready to take cover when the sirens give the alarm. Fortunately the many attempts to bomb the waterworks have as yet been unsuccessful so that a good water supply is still available and no severe epidemics have broken out.

The strictest rationing is in force and though a few food ships have run the blockade there is only ten days' food in hand for the city. For many weeks the people have been living on beans, rice, cabbage and 35 grammes a day of black bread. Owing to the evacuation of the surrounding farms and villages eggs, meat, milk and butter are almost unobtainable. There are small supplies of oranges and olive oil but only a minimal amount of fresh vegetables. There is

no coal, and owing to the air raids, little opportunity for cooking. In many cases it is obvious that the women have starved themselves to provide for the children. One pregnant mother who brought up five healthy looking children for examination was herself so weak she could hardly stand and said smiling that perhaps she would find time to eat when her children were safe in England. Some idea of the state of general disruption caused by the continual aerial bombardment of the town may be gained from the conditions under which the medical examinations had to be carried out. The group of children selected for the Expedition to Inglaterra had been numbered and the first five hundred numbers notified by an announcement in the papers to attend the *Asistencia Social* at 8 A.M. The examinations had hardly begun when the sirens sounded the alarm and the children scattered to the nearest refugio. The air raid lasted 40 minutes. This happened four times during the morning by which time only about sixty children had been seen and the rest had all dispersed. Next day it was impossible to get any to attend for it was Coronation Day and manifestos had been dropped from the air saying that that day would be chosen to bombard Bilbao from air land and sea. The following day it was decided to work in a garden containing a refugio (which served as a convenient dressing room) but even then interruptions were so frequent it became clear that most of the work must be done at night if it was ever to be completed. And so a continuous queue filed by each night until 2 A.M. without the slightest complaint children often attending alone or with an older child and not infrequently unable to get home that night. We cannot speak too warmly of the courage and co-operation both of the children and of their parents. Those who have examined many throats will realise what this implies: not a dozen children out of the whole four thousand cried during the examination and only four had to be held!

RESULTS OF MEDICAL EXAMINATION

The group is not strictly speaking exclusively Basque in origin though the majority are of an obviously different physical type from the southern Spaniards. Many have light brown or even red hair a few are blue-eyed and very few could be described as swarthy. Their facial colouring would usually pass for that of a sunburnt English child. Perhaps the most surprising feature of the examination was the good health of the group as a whole in spite of the conditions of deprivation, anxiety and overcrowding in which they had been living for many weeks. It was evident that even the poorer peasants have a

high standard of care for their children, and that before the blockade almost all the latter were well developed and well fed. It was impossible to weigh and measure the whole group at this time or to apply any strict standards of nutrition, but the impression was definitely gained that although the majority showed loss of subcutaneous fat, the period of malnutrition had not been long enough to cause permanent damage or muscular weakness, and that recovery under proper conditions should be rapid and complete. A few of the smaller children, however, showed really severe marasmus, and were immediately recognisable, even before being stripped, by their blank apathetic faces, their slow movements and whispering speech, and their distended abdomens.

No gross evidence of vitamin deficiency was found with the exception of hyperkeratinisation around the hair follicles, which was relatively common, giving the skin a peculiarly rough feel. It was unfortunately impossible to test for night blindness. The very high incidence of dental caries, however, is probably attributable at least in part to the deficient diet.

Amongst 4090 children examined, the following conditions were noted (furunculosis, impetigo, and pediculæ not being included):

Rheumatic carditis	9	Scabies	13
Old anterior poliomyelitis	5	Ringworm	1
Pott's disease	3	Mumps	2
Otorrhœa	17	Diphtheria	1
Cervical adenitis	17	Bronchitis	4
Hutchinson's teeth	4	Pulmonary fibrosis	1
Clutton's joints and interstitial keratitis	1	Trachoma	2

The two cases of trachoma (occurring in brothers who had come from Valencia) were of course excluded from those allowed to embark, as were the families of those with mumps and diphtheria.

There were also the following congenital abnormalities—

Congenital morbus cordis	2	Congenital dislocation of hip	1
Dextrocardia	1	Congenital absence of pectoralis major	1
Hemiatrophy of face	1		
Inclusion dermoid	1		

Two interesting features of the findings, if compared with any corresponding figures for English school children in the same age group (5 to 15), are (a) the extreme rarity of respiratory infection, and (b) the *entire absence of chorea*. On the face of it, Bilbao would provide sufficient terror, anxiety, and overcrowding to produce chorea in any normal child if these were the only factors necessary, and one is forced to the conclusion that they are not. Amongst a group of 200 young schoolmistresses and nannies, however, examined at the same time, 2 had to be excluded because of early Graves's disease.

Another revealing feature of the group was the appearance of the children's throats. Less than 2 per cent had had tonsillectomies performed, and in a very great number of cases the tonsils were as large or larger than walnuts. But the incidence of both cervical adenitis and otorrhœa was only approximately 0.4 per cent, and that of obvious respiratory infection almost incredibly low. The same is true of nasal discharges and respiratory obstruction. The important question arises as to what will happen to these children now they have reached England. Owing to the difficulty of obtaining parents' consent to operation, it is devoutly to be hoped that they will retain their tonsils, since it might well prove disastrous if these were to be removed before the children had had opportunity of acquiring general immunity to catarrhal infections. (It is also perhaps of interest that of the 200 adults examined none showed appreciably enlarged or unhealthy tonsils.)

THE CHILDREN IN ENGLAND

Having been passed by the port medical authority, the children are at present lodged in camp at Loughborough. It is intended that they shall be drafted from here to homes throughout the country, being kept as far as possible in groups with their appropriate school teachers. Funds are urgently needed for this work, which is being carried out by the National Joint Committee for Spanish Relief in association with the Catholic, Salvation Army, and other organisations. It was impossible not to be touched by the absolute faith the parents had in handing over their children to the care of England. It will surely be the desire of everyone to see that their faith is justified, and that those children who have parents still living return to them under happier circumstances safe and well.

GENERAL MEDICAL COUNCIL

PRESIDENT'S ADDRESS

OPENING the 145th session of the Council on Tuesday last, Sir NORMAN WALKER spoke of the death of two former members, Prof. Theodore Cash and Sir Grafton Elliot Smith, and of Sir William Hansell who served as legal assessor from 1920 to 1927. Sir Henry Dale had unfortunately been unable to accept reappointment as a Crown nominee, and Sir Norman expressed the Council's gratitude to him for successfully guiding their early steps in their close and cordial collaboration with the British Pharmacopœia Commission.

"It is enjoined by tradition," continued the President, "that the summer session shall be primarily devoted to the first object of the Council's existence, medical education, and that they shall deal with disciplinary cases, as a Council of Medical Registration, mainly at the session in November. But in recent years, at any rate, it has seldom been possible to achieve this aim, because the penal cases committee are not in a position to regulate the numbers of cases of convictions of registered medical practitioners reported, or of complaints made, to the Council, which in their judgment call for the holding of inquiries before the Council at the next ensuing session. On this occasion, fortunately, circumstances seem more favourable than they sometimes are, and though a substantial number of disciplinary cases awaits your consideration, none appears likely to be exceptionally lengthy, and time should be available within the week for ample discussion of the reports of the three committees whose work lies in the sphere of medical education."

"The report which will call for the fullest consideration is that of the education committee, who have been dealing with the concluding stages of the revision of the curriculum initiated in 1934. There has been a little variation in method, though not in principle, in the procedure adopted on this occasion. Instead of leaving the matter to the education committee, as was usually done in the comparatively recent past, the executive committee recommended to the Council the appointment of a special curriculum committee composed of the chairmen of the three standing committees on education, examination, and public health, who were individually recognised as authorities on physiology, anatomy, and public health, with the addition of a physician, a surgeon, an obstetrician, and a member engaged in the general practice of medicine. The Council adopted the recommendation

on June 2nd, 1934. The committee elected Dr Tidy as their chairman and commenced work at once reporting progress to the Council in November 1934 and making interim reports in May and November 1935. Constant communication with the licensing bodies was maintained and most of the deans manifested their interest in and their criticism of some of the proposals made. As time went on and all who are familiar with the working of the Council know that in reform of the medical curriculum it is wisest to hasten gently the true meaning of a reform of the curriculum was more and more understood.

This Council is a team composed in the first instance of a representative from each of the licensing bodies. To these are added five nominees by the Crown and seven practitioners elected by the direct vote of the profession in each of the three divisions of the United Kingdom. To the Council is committed a general supervision of medical education and in their early days perhaps the licensing bodies were the only persons actively interested. Admission to the Register was easy in 1858 but in process of time by general agreement among the bodies the minimum curriculum was fixed at three winter and two summer seasons. Then came four years and in 1890 the Council unanimously approved an extension to five years afterwards modified to 57 months mainly because university years were usually of nine months.

On no previous occasion have the proposals of the Council been more thoroughly hammered out on the anvil of discussion and a large measure of agreement has apparently been reached. Thus with certain reservations there seems to be approval of the age of 18 for registration of students.

The question of biology chemistry and physics has always been a problem and I remind the Council that it was only in 1893 that the Council ordained that the first and last of these subjects must be contained in the medical curriculum. Chemistry was defined then as including the principles of the science, and the details which bear on the study of medicine. In 1893 in most parts of the country the teaching of chemistry and physics in schools was of an elementary character and biology only appeared in the curriculum of one or two of them. Times have changed and the chemistry and physics taught in the majority of the schools is of high standard even if it does not include any details which bear on the study of medicine. These must, of course, be learned in medical schools. The teaching of biology of a sufficient standard has not advanced so far as that of the other two subjects. Schools capable of undertaking it are not uniformly scattered over the British Isles and there is a feeling in some quarters that the minds of some young people are perhaps too much devoted to the study of those three subjects to the detriment of their general education.

Here we are helped by the elasticity of our system. If we agree, in order to furnish the requisite knowledge and skill for the efficient practice of the profession that the medical curriculum proper requires to be extended to five years the licensing bodies (all represented here) will frame their regulations accordingly. Already Birmingham Bristol Liverpool Manchester Oxford Wales and University College Galway require six years. Cambridge Leeds, London and Sheffield five and a half and it is common knowledge that others have in contemplation an extension of their curricula. This is the way in which medical education in this country progresses. The Council prescribes a minimum below which no body which wishes to retain its right of admission to the Register may drop but has nothing but a

well done for those bodies which raise the standards for admission to their own degrees.

A vote of thanks to the President for his address was proposed by Mr E W Hey Groves seconded by Dr T G Moorhead and carried unanimously.

Mr Harold Collinson F.R.C.S. representative of the University of Leeds for three years from August 1st 1936 was introduced by Mr R E Kelly.

The Council then passed to the consideration of penal cases.

IRELAND

A SEQUEL TO INOCULATIONS

A DEATH following immunising injections against diphtheria has lately been investigated at an inquest held at Ring Co Waterford. From the evidence given it appears that there is no conflict about the facts. A child of 12 years of age was treated with injections of T.A.F. on Nov 9th 17th and 24th, 1936. She complained of a sore arm early in January 1937 and Dr D T McCarthy of Dungarvan who had given the injections saw her. According to his evidence he found a small discharging ulcer on the site of the inoculation. The axillary glands were enlarged and tender. Her condition deteriorated and the child died on April 20th. An autopsy by Dr W J O'Donovan lecturer in clinical pathology at University College Cork, showed generalised tuberculous infection without meningitis. According to Dr O'Donovan the inflammation on the right arm could not be recognised as tuberculous. Dr McCarthy stated that he had got the material used from Dr O Farrell county medical officer of health. He had inoculated 44 children at St Augustine's College on Nov 3rd 10th and 18th 1936 and no illness resulted. He inoculated 38 children at Ring College on the dates given above and 24 of them were affected. He believed that these 24 were injected in sequence. He gave in detail the precautions which he took for sterilising the instruments with which he carried out the injections, and stated that he had the attendance of a nurse on each occasion. He had no case of tuberculosis in his general practice or in the district hospital at the time. The child, when ill, had been seen in consultation by Dr Casey of Dungarvan and Dr P Kiely of Cork and bacteriological examinations had been made by Dr O'Donovan. He notified the deputy coroner of the child's death. The child's father stated that he had given his consent to the inoculation that he knew that two of Dr McCarthy's children had been inoculated at the same time, that three of his other children had also been inoculated and that they had sore arms. Dr H J Parish bacteriologist to Messrs Burroughs Wellcome and Co who attended the inquest, gave detailed evidence as to the manufacture of T.A.F. and went minutely into the different processes. He contended that their system was error proof. Prof. J W Bigger of Dublin also described Messrs Burroughs Wellcome and Co's laboratories at Beckenham. He was of the opinion that the precautions taken in the manufacture of T.A.F. made it impossible for a live culture of tuberculosis to contaminate the product. The inquest was held by Dr C J Walsh coroner for East Waterford since Dr McCarthy himself was coroner for West Waterford and his deputy was also debarred as he was acting as legal adviser to Dr McCarthy. At the conclusion of the hearing on May 21st Dr Walsh adjourned the inquiry sine die for advice as to his jurisdiction.

AN INDIAN LEPROSY HOSPITAL

(FROM A CORRESPONDENT)

ALTHOUGH in one of the healthiest parts of India, at Coonoor, which is situated in the Nilgiris at a height of 6000 ft. over sea level, one may see on the outer wall of a chemist's shop a large and reassuring announcement to the effect that it sells "the household remedy for all aches and pains," there are other parts of India that have cause to be less happy.

In the largest of the native states, Hyderabad, there is a good deal of leprosy and much is being done under Colonel Norman Walker, director of the Nizam's medical service, to combat this affliction. The annual report of the well-known leprosy hospital at Dichpali makes very interesting reading. In the year ending November, 1936, 903 new patients were admitted, compared with 764 the previous year, while 557 patients passed out of the institution, for lack of space, however, 1209 applications for admission had to be refused. Sir Leonard Rogers wrote in 1933 that "some two thirds of the lepers in the asylums of India are uninfected nerve cases whose isolation does nothing to reduce infections. Yet the public, in their ignorance, still evince the greatest dread of the perfectly harmless crippled lepers with loss of fingers and toes, although they are mostly suffering from the scars of an old 'burnt out' infection." It is because the verdict of scientific opinion is quite clear that the general policy which has been operative in Dichpali since its foundation has been maintained, and only such patients are admitted to the hospital as are likely to respond to treatment. It is felt that the "burnt out" cases are fit subjects not for a hospital but for an asylum, for they cannot face the battle of life unaided. At Dichpali they try to prevent the patients ever reaching the state of mental anguish and physical suffering that is the lot of the victim of advanced leprosy. "We hope," says the report, "that the patients here, after a course of treatment, will be able to return to normal life, and become useful members of society, and we are glad to say that this is generally the case." During the year treatment was carried out along routine lines—i.e., with hydrotocarpus oil and its esters by injection, supplemented by regulated diet and occupational therapy. Gingerly coco nut and ground nut oils, as well as copper sulphate solution, were tried, but it is too early to give an opinion on the permanent therapeutic value of these drugs.

Dichpali is maintaining its reputation as one of the finest leprosy hospitals in India. The Nizam's Government the King's Silver Jubilee Fund the British Empire Leprosy Relief Association and many other friends have been generous in their support so that it has been possible to undertake a heavy building programme. Provision is made at Dichpali

for both work and play. The latest and best methods of farming are taught, while the adult patients undergo elementary education in the adult schools which are held every afternoon. For the children also there are schools where they learn reading, writing, and arithmetic, their gardens provide an outlet for useful manual activity. In the afternoons the boys may be seen playing football, hockey, or badminton with great zest, while in the evenings the time passes pleasantly in dramas, concerts, or at the cinema. Leprosy is now one of the classes attended by students

Sister from Dichpali Leprosy Hospital treating patients out in the villages

of Osmania University—in the capital of the State—proceeding to their M.B., and the State medical department also has continued its usual practice of sending twelve medical officers for post graduate instruction. As a result of this policy, which has been in operation for some years, almost all the medical officers in the Nizam's Government Medical Service are skilled in the diagnosis and treatment of leprosy.

AUSTRALIA

(FROM OUR OWN CORRESPONDENT)

AUSTRALASIAN COLLEGE OF PHYSICIANS

THE Australasian College of Physicians, which is being formed, includes in its scope both the Commonwealth of Australia and the Dominion of New Zealand and it is proposed to model it as far as possible along the lines of the Royal College of Physicians of England. Amongst its objects is the management of post graduate study in medicine, requiring of candidates for admission to the College evidence that they have given intensive study to advances in knowledge in medicine. Regular scientific meetings will be also held.

It was unanimously determined, at a meeting of representative physicians from New South Wales, Victoria, Queensland, and South Australia, that Sydney should be the site of the building of the College. The Government of New South Wales offered to provide £25,000 towards the foundation of the College and the University of Sydney offered a site on which the building could be erected within the precincts of the University. It was, however,

subsequently decided by the Committee of Physicians that it would be more suitable to have the College situated in a more central position in the city. A committee appointed has purchased a building in Macquarie-street the old home of the Warrigal Club.

Certain Victorian donors have signified their intention to provide at least £20 000 to initiate a fund for the permanent endowment of the College when completed. Considerable progress has been made in raising further sums of money for alterations

to the building and for the maintenance of the College when its activities begin.

INFANT MORTALITY IN SOUTH AUSTRALIA

Vital statistics for 1936 show that during the year infantile deaths in South Australia have decreased to the record low rate of 31.08 per 1000 births. In 1935 the rate was 34.95 per 1000. The present death rate is less than half the rate of twenty years ago and about a third of the rate in 1900.

CORRESPONDENCE

MEMORIAL TO THE LATE PROF E H KETTLE, F.R.S

To the Editor of THE LANCET

SIR,—By the death of Edgar Hartley Kettle in December last, pathology in this country lost one of its most distinguished exponents and all who knew him were deprived of a personal friend. We feel sure that those who were associated with him, as colleagues or students in his professional work or in any other of the activities in which he took part, would desire that his memory should be perpetuated in some suitable form.

Kettle's devotion to his subject and to all that concerned it including particularly the interests of his students and younger colleagues was evidenced throughout his professional career. As an original worker, as a director who stimulated the work of others, as a teacher as a senior member and treasurer of the Pathological Society and as an active member of numerous committees he played a part that will not be forgotten. In each of the four university schools in which he directed the teaching of pathology, St. Mary's, Welsh National School of Medicine, St. Bartholomew's and the British Postgraduate Medical School he won the admiration and affection of his colleagues and his students. We feel that a fitting tribute to his memory would be the foundation of a Kettle Memorial Lectureship in Pathology and that this lecture might appropriately be given annually in each of these schools in turn.

An endowment fund is being collected for this purpose, and we are sure that his colleagues and friends, including many who though not pathologists were associated with him in connexion with his pioneer work on silicosis or in other ways would wish to be given the opportunity of contributing. It is suggested that individual contributions should not in most cases be more than two guineas and smaller sums will be welcomed.

Contributions should be sent to the Treasurer Kettle Memorial Fund British Postgraduate Medical School Ducane-road W12. Cheques should be drawn in favour of the Kettle Memorial Fund and crossed Barclay & Co.

We are Sir yours faithfully

OBSTETRICS IN GENERAL PRACTICE

To the Editor of THE LANCET

SIR,—Those who sincerely desire an improvement in our maternity services will be grateful to Prof. Munro Kerr for his letter in your last issue which brings out just the essential points. Most practitioners with experience of general practice realise that owing to the greatly increased demands made on their time since the introduction of the National Health Insurance Act they can no longer give adequate attention to midwifery. Midwifery is now full time work and if we are to avoid the criticism which appears again and again in the Maternal Mortality Report of the Ministry of Health that antenatal work is defective we must have one practitioner with time at his or her disposal responsible for each patient, before during and after her confinement.

I was particularly pleased that Prof. Munro Kerr mentions the need for institutional treatment for primigravidae because public health authorities responsible for the provision of maternity hospitals while most anxious to do what is right are too often advised that midwifery in the home is safer than midwifery in hospital with the result that in most counties maternity hospital accommodation is totally inadequate.

Prof. Munro Kerr is a recognised leader in his profession will he lead the general public to achieve better maternity services?

I am Sir yours faithfully

Station road New Barnet, May 21st. JOHN ELAM.

PERNICIOUS ANÆMIA IN AN INFANT

To the Editor of THE LANCET

SIR,—Dr Hawksley's letter in your issue of May 15th in which he supports the diagnosis of pernicious anaemia of infancy in the case recorded by Langmead and Doniach raises several points that are of interest. First he emphasises the presence and importance of achlorhydria in Langmead's case, yet it is well known that during infancy the gastric acidity is extremely variable that it is frequently low and that in association with ill health especially infectious disease achlorhydria is commonly found.

In answer to my letter of May 8th Dr Hawksley suggests that if at a later date the infant is able to thrive without liver therapy it may be presumed that the so called 'pernicious anaemia' was caused by a temporary cessation of ability either to elaborate or to absorb the anti-pernicious anaemia factor. This may or may not be the explanation but it is hardly justifiable to label a temporary upset in secretion of intrinsic factor true pernicious anaemia—a disease that occurs almost exclusively during the second half of life and in which inability to elaborate the

anti-anæmic factor is permanent Dr Hawksley mentions the analogous situation which may arise in celiac disease, but he will I think agree that we do not label that condition pernicious anæmia.

Among the cases investigated by me, of hæmolytic anæmia of infancy and childhood which showed macrocytosis, the case in which the macrocytosis was most marked and which recovered with the greatest rapidity with liver therapy had a high gastric acidity. In view of this finding it was thought possible that, as a result of prolonged hæmolysis and increased red cell production, the liver factor was temporarily exhausted and that consequently a macrocytic anæmia developed which responded to liver therapy.

I am, Sir, yours faithfully,

Birmingham, May 22nd W CAREY SMALLWOOD

CARCINOMA OF THE STOMACH

To the Editor of THE LANCET

SIR,—In his article on gastric and duodenal ulcer, which appeared in your last issue, Dr Duncan Leys states that "carcinoma of the stomach is mercifully a relatively uncommon disease." But relative to what? If it be a cold in the head or measles in children the answer may be "Yes," but if it be to gastric disorders of middle age—or indeed to any disease of middle age for that matter—the answer is most emphatically "No." I submit that a truer statement would be that carcinoma of the stomach is mercilessly a common disease, whether the word relatively be used or not.

I have to hand the notes of 25 cases which I saw at King's College Hospital during the first eleven months of 1936 alone. Analysis of these cases speaks for itself. No less than 9 of them were clinically inoperable, and of the remaining 16 which were explored, the radical operation was practicable only in 5. The average duration of symptoms in these cases was one year and eight months—another eloquent fact.

Dr Leys's unhappy experience of surgery in this disease is, however, by no means a fair representation of surgery as a whole. He writes "in six years of busy hospital practice, I have not seen a single patient with carcinoma of the stomach whose life has been usefully prolonged by surgery." Most surgeons can claim at least that "lives have been usefully prolonged" by the radical operation in proven cases of carcinoma of the stomach. In a comparatively short experience I can from my own series quote one case alive and well four years and eleven months after operation, and several of shorter duration. Length of history, as is well known, is not always an indication of operability. None the less, surgery could do far more did the cases reach the surgeon earlier. As regards differential diagnosis from other disorders of the stomach—not only peptic ulcer but also chronic gastritis—I would commend the use of the gastroscope as a most helpful adjuvant to radiology.

Figures from the gastric clinic at King's College Hospital, where the cases are primarily seen by my colleague Dr Charles Newman, bear out the experience of Dr Leys as regards the relative frequency of gastric and duodenal ulcer. During the first eleven months of 1936 there attended 82 new cases of gastric ulcer and 61 new cases of duodenal ulcer, including 2 of duodenal stenosis. During the same period there were 21 cases of gastritis.

I am, Sir, yours faithfully,

London W May 20th HAROLD C EDWARDS

"POPULAR" NAMES OF DISEASES IN DEATH CERTIFICATES

To the Editor of THE LANCET

SIR,—The extract from THE LANCET 100 years ago (May 27th, 1837) in your last issue is of much interest. Probably the letter signed by the medical grandees was composed by Farr and the explanatory statement (which is printed on p. 211 of the volume of excerpts from Farr's writings published by the Royal Sanitary Institute in 1885 under the title "Vital Statistics") is pure Farr. The leader writer scores a good debating point enough, but Farr might probably have retorted that his proviso "whenever the popular name will denote the cause of death with sufficient precision" met the real objection. The development of Farr's policy in the matter of registration can be followed very well in the volume of excerpts quoted above. Remembering that Farr himself had any amount of intellectual courage verging, as his successor Ogle evidently thought, on temerity, it is noteworthy how cautious he was in imposing rules of nomenclature. As late as the Sixteenth Annual Report he flatly declined to put an official ban on dropsy. "The permission to use vague terms in these cases, it is objected, encourages negligence, but the refusal to recognise those terms that express imperfect knowledge has an obvious tendency to encourage reckless conjecture." I stoutly resist the temptation to display my King Charles's head on a charger with the label *status lymphaticus*, and content myself with remarking that Farr's conservatism was a great virtue.

I am, Sir, yours faithfully,

Loughton May 22nd

MAJOR GREENWOOD

THE PATELLA

To the Editor of THE LANCET

SIR,—Many surgeons must have had their former conceptions of the functions of the patella rudely shaken by Mr Ralph Brooke's article in the current number of the *British Journal of Surgery*. That the patella can be removed and the power of the knee increased seems to go against all that was taught us in our anatomy studies, yet this is what Mr Brooke has now demonstrated. The explanation of this anomaly is brought out by Prof Hey Groves's paper in the same journal, and it would appear that we must now look upon the patella as a rudimentary structure, a back number like the appendix. Surely this new conception of the mechanics of the patella is aptly to be stated by saying that the patella is a sesamoid bone, not in the tendon of the quadriceps but deep to it, or underneath it. When one dissects back the quadriceps expansion in the new operation of removal, one is surprised at the thickness of the tendon over the patella compared to the lateral expansions—the capsule that one cuts through in the removal of a semilunar cartilage.

The surgeon is sometimes surprised that a patient with a comminuted fracture of the patella due to direct violence is still able to use the knee. The reason for this is now made clear, as the following case brings out.

A clerk aged 50 slipped on some railway stairs hitting his knee cap several times as he fell downwards. He was able to get up, catch his train, and do a day's work. Next day as the knee was swollen he consulted his own doctor and was advised to rest for a few days till the fluid went down. However when he started to use the knee again the fluid returned with a little discomfort, though he was able to walk a mile or so to the station each day. After nearly a fortnight he was advised to come up to hospital. When

he came into the out-patient room he walked with a slight limp, but was able to flex and extend the knee to nearly its full range. The tenderness of the patella suggested a chip off this bone. Radiography however showed a comminuted fracture. As he seemed a suitable case operative removal was decided upon.

When I exposed the patella I found that the prepatellar aponeurosis and the lateral expansions were intact. On incising this I was surprised at the cuff of aponeurosis nearly a quarter of an inch thick which I had to reflect back over the patella to reveal the fragments beneath. This was very different from the frayed ends which one endeavours to sew up in operating to wire a transverse indirect violence fracture. After removal of the bone this aponeurosis came together with ease and when sewn up was certainly as strong as the tendo Achillis. One saw how with this aponeurosis intact the mechanical power of the quadriceps was but little impaired once there was some power of adhesion between the fractured surfaces and the surrounding hematoma so that a pulley action was again possible round the lower end of the femur.

It would be interesting to know the experience of other surgeons with this new operation; both in the case of comminuted and in transverse simple fractures. I am indebted to Mr Alan Todd for kindly allowing me to operate on this patient.

I am, Sir yours faithfully

THE LIMITED FIELD OF CANCER RESEARCH

To the Editor of THE LANCET

SIR,—A perusal of the thirteenth annual report of the British Empire Cancer Campaign leaves one with the feeling that, as far as treatment by radiation is concerned, too large a share of the available workers and resources is being concentrated on the use of radium and super voltage X ray therapy, a share altogether out of proportion to any reasonable expectation of what can be achieved by these agents, to the detriment of other lines of research. I doubt whether the most optimistic of radium therapists ever hope for so much as a 50 per cent. five year cure of all cases of cancer referred to them for treatment. All experience so far recorded of the use of super voltage X ray therapy indicates that the most to be expected is possibly slightly better results in a very limited class of cases.

The construction of such costly forms of apparatus as radium bombs and super voltage X rays generators would only be justified, beyond one or two acts for experimental purposes, if there were substantial reasons for believing that it would lead to a great advance on all previous methods in controlling cancerous growths. There is no convincing argument in favour of such an expectation. The only justification for this outpouring of treasure and effort is an assumption that the gamma rays of radium possess a greater therapeutic value than X rays which is due to their shorter wave-length, and hence the shorter the wave length of X rays the greater their usefulness.

That radium has been used with more success than X rays in the treatment of malignant disease in certain situations no one will deny, but in these cases besides the difference of the wave length of the radiation there are other important variant factors which are known to exert a powerful influence on the results. To assume that the shorter wave length is the only factor responsible for the better results or even that it is a contributory cause is illogical.

The cavities of the body are the situations in which radium can be used with the greatest advantage because it can be placed in contact with the growth

and its radiation is diminished in intensity before reaching the subjacent healthy tissues. This alone might account for better results, but there is also the time-intensity factor. For a dose of equal intensity a much longer time is required when using radium than when using X rays. This dissimilitude can be lessened by splitting the X ray dose into a number of small daily doses and this practice has been followed by greatly improved results, proving that the time during which the growth is under the influence of radiation is of great importance. By means of the Chaoul technique, brilliant results have been obtained with X rays of long wave-length by bringing the source of radiation very close to the growth—further strong evidence against the assumption that wave length is a factor of importance.

It would be neither a very difficult nor a very costly experiment to compare the action of X rays and gamma rays with the time intensity factor eliminated. By means of a long shield—say an length up to ten feet—the X ray tube could be used at such a distance from the patient and the current could be so adjusted that the intensity of the radiation would be the same as that received from a radium pack in short with X rays the time-intensity factor is entirely under our control.

The assumption that the gamma rays of radium have a therapeutic value that can only be equalled by X rays of equally short wave-length, when they can be generated, is based mainly if not entirely on impressions—they are the impressions of those working with radium and we know quite well that there are very few workers who are free from a strong bias in favour of their own methods. The arguments against this assumption is based on facts. Experiments with drosophila eggs and other test materials go to show that biological reaction is independent of wave length. Then there is the brilliant success of the Chaoul technique in which the X rays are generated with a voltage of only 60 000. And there is also the fact that the results obtained at Erlangen by treating uterine carcinoma with X rays only compare very favourably with the results obtained by the combined use of X rays and radium.

And the claim that super voltage X ray therapy is an advance of any value was to my mind finally disposed of at the thirty-sixth annual meeting of the American Roentgen Ray Society in September 1935. At this meeting after the reading of papers recording poor results of this method Dr Carter Wood of New York City said it would be well to confine the construction and operation of these very expensive forms of apparatus to those now installed in the institutions in various parts of the country. Dr Ruggles whose name is well known also in this country speaking of a year's experience with 800 kv X rays said "From what can be observed in the routine of a clinic they (the patients) do about as well as those treated at 200 kv."

Neither theoretically nor from practical experience have we any reason to expect any outstanding advance in the treatment of cancer by the use of X rays of very short wave length.

At the same meeting of the American Roentgen Ray Society an account of which is well worth the study of those controlling research in this country a paper was read by three radiologists reporting three cases two of advanced carcinoma mammae one of which had wide-spread bone metastases and one of lymphoecarcinoma involving the lymph nodes of almost the entire body, all well and clinically free from disease five years after treatment. The treatment

was X radiation of the whole body and endocrine glands extending over a year. In view of the uncertainty of the effects of whole body radiation only these three cases had been treated up to two years ago. Here is a method by which there is some possibility of a great advance, yet there is nothing in the report of the British Empire Cancer Campaign about research in this direction, nor the radiation of large areas of the body with a view to increasing the patient's resistance to the cancerous invasion and increasing the radio-sensitivity of malignant growths.

I am, Sir, yours faithfully,

Dover, May 22nd

WILFRID GARTON

TRACHOMA IN REFUGEE CHILDREN

To the Editor of THE LANCET

SIR,—Lord Lloyd in the House of Lords last night performed a public service by asking a question as to the incidence of trachoma among the refugee children from Spain who have arrived in this country. It is known that in many of the provinces of Spain the disease is practically universal. Lord Lloyd was informed that a voluntary body called the National Joint Committee for Spanish Relief sent out some doctors to examine the children before they left Bilbao. It is not reported that any of these gentlemen had any experience of trachoma or even any special knowledge of ophthalmology. The examination of the eyes of 4000 children by port medical officers on arrival at Southampton was an absolute impossibility. It is therefore still unknown what proportion of the children if any is trachomatous. The difficulty in making a diagnosis in the early stages of the disease, its contagious nature, the long period required for treatment, and its devastating effects on visual acuity make it important to decide the matter.

If the children are to be kept segregated in a camp no danger will accrue to the surrounding inhabitants. On the other hand, if a few of them are trachomatous and are temporarily placed in Salvation Army or other homes in contact with other children there is every expectation of a recrudescence of the disease in this country. In this matter the responsibility of the Ministry of Health is very great.

I am, Sir, yours faithfully,

A F MACCALLAN,

President of the International Organisation
against Trachoma

London May 26th

MIDDLE-EAR DISEASE IN INFANCY

To the Editor of THE LANCET

SIR,—I was very interested in the leading article in your last issue. At the Hospital for Sick Children, Great Ormond street, it has been recognised for some years that pus in the middle ear and mastoid is a frequent autopsy finding, especially in infants dying of gastro enteritis. I have just looked through the post-mortem records of the past two years and observe that out of the 170 autopsies in which the middle ears were examined, just over 50 per cent had pus in one or both. This agrees closely with Dr Ebbs's figures for a much larger series. All but a small proportion of these positives were in children under two years of age. Another fact that emerges is that a much higher proportion of children dying from gastro enteritis have pus in their middle ears than those dying from other diseases. Thus 33 (65 per cent) out of 43 cases of gastro enteritis had one or both ears infected whereas of 100 children under two dying of some other disease only 44 had pus in one or both middle ears.

From these figures it seems that the infant suffering from gastro enteritis is particularly liable to a middle

ear infection. The gastro intestinal infection is, I think, undoubtedly in some cases secondary to the otitis media, but, in my view, in the majority of cases the otitis supervenes during the course of the gastro enteritis and, as Dr Ebbs suggests, may contribute to the fatal issue.

All who have to deal with these patients know how difficult of diagnosis the otitis media may be. Not only are there no symptoms but frequently the appearance of the drum is normal. It must be a common experience for the ears to be pronounced normal only to find them full of pus at the autopsy a day or two later. One should never hesitate to incise a drum should there be any suspicion, such as a sudden unexplained rise of temperature would provoke, that the middle ear has become infected.

The ventilation of this difficult subject at the Royal Society of Medicine discussion should stimulate both otologists and paediatricians to coöperate in investigating this widespread malady.

I am, Sir, yours faithfully,

G H NEWNS

Hospital for Sick Children, Great Ormond street,
May 25th

A REMEDY FOR HÆMORRHOIDS

To the Editor of THE LANCET

SIR,—In your issue of May 22nd (p. 1261) you refer to a very recent paper in the *Revista sud americana de endocrinologia, inmunologia y quimio-terapia* in which an oily solution of an extract of the earthworm *Microcolex dubius* (Fletcher) is recommended as a remedy for piles. It may perhaps interest your readers to learn that this is a very ancient treatment. Stephenson, in his monograph on the *Oligochaeta*, quotes Damiri, the author of an Arabic treatise on the life of animals written in A.D. 1371, as saying that suppositories made from earthworms fried in olive oil and powdered are highly beneficial to persons suffering from piles.

I am, Sir, yours faithfully,

C C A MONRO

British Museum (Natural History) Cromwell road,
S W May 22nd

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED
MAY 15TH, 1937

Notifications.—The following cases of infectious disease were notified during the week. Small pox, 0; scarlet fever, 1440; diphtheria, 781; enteric fever, 24; pneumonia (primary or influenzal) 798; puerperal fever 26; puerperal pyrexia 108; cerebro-spinal fever 30; acute poliomyelitis 5; acute polio encephalitis, 2; encephalitis lethargica, 5; continued fever, 1 (Nuneaton); dysentery, 16; ophthalmia neonatorum 76. No case of cholera, plague or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 21st was 2967 which included scarlet fever 783; diphtheria 846; measles 76; whooping-cough 496; puerperal fever 17; mothers (plus 12 babies) encephalitis lethargica 83; poliomyelitis 0. At St Margaret's Hospital there were 20 babies (plus 12 mothers) with ophthalmia neonatorum.

Deaths.—In 123 great towns including London, there was no death from small-pox. 3 (0) from enteric fever, 13 (0) from measles, 3 (0) from scarlet fever, 20 (0) from whooping cough, 19 (3) from diphtheria, 57 (13) from diarrhoea and enteritis under two years, and 36 (5) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever were at Portsmouth, Southampton and Southend-on-sea. Liverpool reported 3 deaths from whooping cough. Diarrhoea was fatal in 3 cases each at Liverpool and Nottingham.

The number of stillbirths notified during the week was 277 (corresponding to a rate of 13 per 1000 total births), including 51 in London.

OBITUARY

FREDERICK EDGE M.D. M.R.C.P. Lond.,
F.R.C.S. Eng.

Dr Frederick Edge who died at Wolverhampton on May 17th was born in Russia in 1863 the son of William and Mary Pollitt Edge. He was educated at Owens College Manchester and St. Thomas's Hospital, London qualifying in 1886 and taking higher diplomas after further study at Munich, Vienna and Dresden. Five years after qualifying he settled in Wolverhampton and was shortly appointed honorary surgeon to the Women's Hospital then in St. Mark's road. A few years later he joined the staff of the Birmingham and Midland Hospital for Women and on both these hospitals he served for thirty years or more. Later he was attached to the Birmingham Maternity Hospital and examined for the Central Midwives Board. Before his hospital appointments because too pressing he was a member of the Wolverhampton town council. He married the daughter of Isaac Bradley of Codsall House Staffordshire, and leaves two sons and a daughter.

J. H. S. writes. In the week that Frederick Edge died there appeared in *THE LANCET* an article entitled 'Perspective and Poise in Practice'. These words epitomise the whole personality of Dr Edge for he possessed these qualities in relation not only to practice but to the art of living itself. Endowed with an unusual facility for friendship which found no difficulty in bridging a disparity of years amounting often to half a lifetime, the love and veneration in which he was held is no matter for surprise. His passing touches many of us deeply. To these qualities was added a certain flavour of individuality—both in point of view and its expression—which derived perhaps from the mixture of Slav and Saxon temperament in his veins and added point to his personality marking him off from the mean of the normal man. His professional life was spent in Birmingham and Wolverhampton. To the latter town (from which these notes have been written) his services were immense. To mention but one point from the many that spring at once to mind the fusion of two hospitals is rarely accomplished without friction between the numerous personalities involved but the amalgamation between the Royal Hospital and the Women's Hospital at Wolverhampton was saved from this very largely through the presence of Dr Edge in our midst. He was made the first chairman of the medical committee of the new hospital and so rare a power did he show of smoothing difficulties and of keeping us all not only happy and agreeable but—so rare in such committees—to the point as well that what had invariably been a yearly tenure was in his case by unanimous desire made into a triennium. Whether in practice at the bridge table at the deciding putt on the 18th green or in the presence of some administrative or other difficulty Frederick Edge was a connoisseur of life with a zest—and a sagacity—all his own. We shall not easily see his like again.

JOHN POLAND F.R.C.S. Eng.

With the death of Mr Poland at his home at Seal Kent on May 22nd medicine loses a distinguished orthopaedist and London a distinguished citizen. Mr Poland was grandson of a Sheriff of London he was himself a Master Skinner and one of his sons is City Marshal. Born at Blackheath in 1865, he qualified from Guy's Hospital in 1870 taking the

F.R.C.S. Eng. three years later. He was demonstrator of anatomy and surgical registrar at the hospital going on to the Queen's Hospital for Children where he was registrar and anaesthetist. He attached himself to the Miller General Hospital at a time when it was emerging from the Royal West Kent Dispensary and became its senior surgeon holding also similar positions at the Royal National Orthopaedic and the City Orthopaedic Hospitals. He edited and brought up to date the collected lectures on 'Bodily Deformities' delivered at the latter by his predecessor E. J. Chance adding two lectures of his own on club foot and he was for many years surgical secretary of the Hunterian Society delivering the Hunterian oration in 1901 and becoming president in 1906. Mr Poland was 81 years of age. His wife a daughter of James G. Denham predeceased him in 1932.

RICHARD THOMAS WILLIAMSON, B.Sc. Vict.
M.D., F.R.C.P. Lond.

Dr R. T. Williamson who died on April 28th at his home in Surrey had retired twenty years ago from his position as physician and neurologist in Manchester and the announcement of his death will recall to the older generation the memory of a wise clinician, a stimulating teacher and an ardent seeker after truth. Williamson was a Lancashire man by birth and education. He did his schooling at Burnley and Owens College Manchester qualifying in 1884 when he was only 23 years old. He was house physician at the Infirmary went on to demonstrate physiology at Birmingham and to take a house appointment at the National Hospital, Queen's square. Having there gained a taste for neurology it remained his primary interest in medicine when he returned to Manchester to work his way up to staff appointments at Ancoats and the Royal Infirmary. His earliest publication however was a monograph on diabetes. Dreschfeld, in his lecture course of medicine left to Williamson the whole department of neurology. In 1908 Williamson published his *Diseases of the Spinal Cord* a book which was illustrated more profusely than almost any medical book of that time and its success was such that a second edition was called for within a few years. None of his colleagues at the Infirmary used the ophthalmoscope in diagnosis of disease to anything like the extent he did and he was the first one of them to examine the fundus by direct vision using an unenclosed candle as his means of illumination. He did a great deal of practical laboratory work, fixing, cutting, staining his own specimens and drawing illustrations from them for use in papers or book. His health was never robust and in 1917 when 55 years of age he was obliged to give up his active professional life. Retirement to the south gave him the opportunity

DR WILLIAMSON

for historical writing, the taste for which dated from a visit to Vienna in his student days. Many stories and short sketches appeared in a New York journal, and in 1927 he embodied some of his own experiences in a book entitled "The Log of an Old Physician."

A colleague writes: "Many students of the Manchester Medical School will have friendly and happy memories of the work they did with R. T. Williamson. He was ever ready to help in the difficult paths of medicine and though his lectures might go beyond the understanding of his audience his bedside help—freely given—was always of the greatest use and benefit. He delighted in tackling a difficult case and in the end his opinion was usually right. Though he was unimpressive on first acquaintance and retained the speech and mannerisms of his native county to the end, his kindness and his knowledge made a deep impression on those who knew him. Medically his chief interests were in neurology and in diabetes mellitus. In both of these subjects he did keen research work, relying on his own examinations and estimations in all that he did. His published books are full of original observations, pictures, and diagrams. The treatment of diabetes brought him a large practice. Later in life he took a keen interest in school hygiene and after his retirement from practice, when he had settled in Barnes, he turned to history, spending long hours at the British Museum."

"There was much that was tragic in his life. Naturally of an introspective nature he was saddened by two events—the death of his mother, who was killed in a street accident, and that of his wife—who

was of Thuringian birth—who died with thrombosis after a minor surgical operation. His later thoughts often turned on the ways these two deaths might have been avoided."

The picture is from a photograph in the Manchester University Medical Library taken before his retirement.

JAMES ADAMS, M.D. Aberd., F.R.C.S. Eng.

THE death at Eastbourne on May 10th of Dr James Adams removes the elder of two brothers, both of whom qualified from St Bartholomew's Hospital in the early 'seventies. James was born near Salcombe, Devon, in 1850, and was educated at the University of Aberdeen. After qualification he was resident at the West London Hospital and at the Brooke House Asylum, Clapton, before returning to Devon to practise at Ashburton, where he was surgeon to the local hospital and became chairman of the West Country Association. In 1888 he took the F.R.C.S. Eng. and moved to Eastbourne, where he spent the remaining 50 years of his life. He was attached for many years to St Mary's Hospital, where he had the reputation of being a specially skilled operator. Many short contributions to our own columns indicate the wide range of his surgical interest. For some time he was deputy medical officer of health. In private life he was a man of social gifts, keen on gardening and skilful at chess, presiding over the Eastbourne Chess Club. His wife predeceased him, and his only son is senior surgeon at Penang. His brother, Mr John Adams, F.R.C.S., is still living in London.

ROYAL INSTITUTE OF PUBLIC HEALTH AND INSTITUTE OF HYGIENE

Lord Horder presided over the inaugural meeting of the Congress of the Royal Institute of Public Health and the Institute of Hygiene which was opened at Margate on May 25th. In his address on health education, Lord Horder pointed out that the healthiness of the individual was bound up with the art of living and was inseparable from the conduct of life. He emphasised the importance of the formation of sound habits, which must of necessity be first inculcated by the parent. Touching on the relation of medicine, first in its study and then in its application, he maintained that the function of the doctor should be more educative than corrective; healthiness is a positive concept, not merely the absence of disease. Lord Horder summarised the rôle of local authorities and their staffs in combating infectious disease, in protecting foodstuffs, in securing satisfactory shelter for the individual and the provision of fresh air and pure water, all powerful factors in promoting health. Nevertheless he submitted that to aim at extending life was not everything—not even the main thing—the chief problem being how to live more happily. He considered that just as we can organise for defence, we can organise for health and happiness.

While admittedly great strides had been made much more remained to be done. Although adulteration of food was controlled, we had not yet begun to tell the people what foods they required for health. Though occupational disease had been reduced, occupational fitness had also diminished. In a list of conditions calling for remedy he included crowding, fatigue, the conditions of railway travel and the prevalence of preventable noise. The maternal mortality rate, the high incidence of tuberculosis

in young women, and the appalling ravages of minor illnesses which result in loss of time and wages must also be reduced. He advocated the extension of insurance to the families of the workers and urged the care of the pre-school child, pointing out that preventive medicine was most active when it concerns itself with those matters on which public opinion and attention have already been directed.

At the conclusion of the meeting two presentations were made by Lord Horder. The first was the Harben medal, given by the Institute of Hygiene every third year as a reward for eminent services. The recipient this year was Sir Gowland Hopkins, F.R.S. The other was the Smith award, given triennially by the terms of the trust to the medical officer of health who was deemed to have performed the most noteworthy work in the department of preventive medicine. This (second) award was made to Dr Charles S. Thomson, medical superintendent officer of health, City of Belfast.

THE LANCET 100 YEARS AGO

May 27th, 1837, p. 351

ROYAL MEDICAL AND CHIRURGICAL SOCIETY

From a contribution made by Dr J. JOHNSON to a discussion on nervous affections peculiar to young women, causing contraction of the muscles of the extremities, accompanied by increase, diminution or absence of sensation, or motion held at the Royal Medical and Chirurgical Society on May 27th 1837.—Dr BRIGHT, President.

The cases of Dr Wilson proved that hysterical affections particularly in young women might simulate organic disease occurring in every part from the head to the foot even taking on the character of white swelling, loss of vision &c. He thought the author had acted wisely in advancing no theory on the subject, the idea of the uterus wandering from one part of the body to another, was as good as any that had been adduced.

TUESDAY, MAY 25TH

Officers Invalided Out of the Army

Mr CHORLTON asked the Secretary of State for War the number of officers invalided out of the Army as a result of accident or sickness during their first 10 years of service in the years 1933, 1934, and 1935 or the latest convenient dates—Mr DUFF COOPER replied: The numbers for 1933, 1934, 1935, and 1936 were 6, 6, 4, and 6 respectively.

Housing in Scotland

Mr BARR asked the Secretary of State for Scotland what was the total number of houses completed in Scotland with State assistance from 1919 till March 31st 1937 or the last available date and the total amount of State subsidy paid in respect thereof—Mr ELLIOT replied: The total number of houses completed in Scotland with State assistance from 1919 till March 31st, 1937, is 215,537. The total amount of State subsidy paid up to that date is £23 549 148.

Treatment of Tuberculous, Crippled, and Orthopaedic Cases

Mr WILSON asked the Secretary of State for Scotland the annual cost for the treatment of tuberculous crippled, and orthopaedic cases—Mr ELLIOT replied: Local authorities in Scotland incurred a net expenditure of £640,670 on the treatment of tuberculosis in the year 1934-35, the latest year for which information is available. Orthopaedic and cripple cases are dealt with by local authorities under their tuberculosis, child welfare, and

school health schemes but I regret that a separate figure for this expenditure is not available.

A Factory Code

Mr RHYE DAVIES asked the Home Secretary whether in view of the complexity of the Factories Bill, he would issue from his department, when the Bill became law a Factory Code as a plain guide to the new Act, somewhat similar in character to the Highway Code—Mr R. S. HUDSON, Parliamentary Secretary to the Ministry of Health, replied: It will clearly be necessary to issue some kind of explanatory statement. I cannot anticipate now what form it may take, but the hon. Member's suggestion will be borne in mind.

Staffordshire Hospital Arrangements

Mr MANDER asked the Minister of Health the present position with regard to the Staffordshire county council scheme for dealing with invalids and old persons which came into operation on April 1st in Wednesfield, Willenhall, and other districts, whether a reply from the council to his letter had now been received, and whether there was yet a resident medical officer at the Wordsley institution—Mr HUDSON replied: I understand that the position remains as stated in the reply given to the hon. Member's question on this subject on April 8th, and that the county council will not have an opportunity of submitting a report to my right hon. friend until after their next meeting in July. As regards the last part of the question, I am informed that there is now a temporary medical officer resident at the Wordsley institution pending the making of a permanent appointment.

MEDICAL NEWS**University of Oxford**

Dr A. G. Gibson, reader in morbid anatomy in the University, has been constituted Nuffield reader in morbid anatomy while holding the office of honorary pathologist at the Radcliffe Infirmary. He will receive a stipend of £500 a year. Dr B. G. Macgrath has been appointed university demonstrator in pathology from May 1st, 1937, to Sept. 30th, 1941.

University of London

Mr John Kirk has been appointed from Oct. 1st to the S. A. Courtauld chair of anatomy tenable at the Middlesex Hospital medical school.

Mr Kirk is 55 years old. He graduated M.B. at the University of Edinburgh in 1904 and after holding hospital appointments was engaged in medical missionary work in China from 1907 to 1928. In the East he continued his studies in human anatomy and when the new buildings at the Kung Lee Medical College, Canton, were opened in 1924 he was invited to organise and take charge of the department of anatomy which was the first of its kind in South China. During the first of his two periods of furlough (1913-14) he was admitted a fellow of the Royal College of Surgeons of Edinburgh and during his second furlough (1921-22) he was a full time demonstrator in the University of Birmingham. For six years he was a member of the council of medical education of the China Medical Association, was chairman of the Association during the biennium 1927-28, and president from 1925-27, and he acted as chairman of the joint conference of the Chinese Association and the Hong Kong and South China branch of the British Medical Association held at Hong Kong in 1925. In 1920 he visited Canada and the United States as a member of a delegation financed by the Rockefeller Foundation for the purpose of reorganising support in these countries for the Canton Hospital as a centre of medical education in South China. He returned to England in 1928 and since then he has been on the staff of University College, London from 1928-30 as a full time demonstrator of anatomy and since 1930 as senior demonstrator. For the past six years he has also had charge of the class of anatomy preparing students for the primary F.R.C.S. examination. He is also sub-dean of the faculty of medical science of University College and for the past four years has had the additional duties of senior tutor in the faculties of medicine, science, and engineering.

The title of professor of morbid anatomy in the university has been conferred on Dr W. D. Newcomb in respect of the post held by him at St. Mary's Hospital medical school.

Society of Medical Officers of Health

Dr James Fenton, medical officer of health for the Royal Borough of Kensington, has been elected president of this society for the session 1937-38. Dr Fenton is chairman of the Central Council for Health Education and is a past chairman of the Royal Sanitary Institute.

University of Egypt, Cairo

Dr A. Cecil Alport has been appointed professor of clinical medicine and director of the medical unit of the university.

Dr Alport graduated in medicine at the University of Edinburgh in 1906 and during the war worked in the 28th and 41st General Hospitals and at the Royal Herbert Hospital, Woolwich. He also acted as specialist in medicine to the latter hospital and as consultant in tropical diseases to the Ministry of Pensions. In 1919 he took his M.D. degree at Edinburgh and in 1920 he became a member of the Royal College of Physicians of London. He was elected to the fellowship this year. Dr Alport at present holds the position of assistant to the director of the medical unit of St. Mary's Hospital. He published a text book on nephritis in 1920 and has also written on malaria and splenic anaemia.

Commonwealth Fund Fellowships

Commonwealth fellowships in medicine have been awarded to Dr D. M. Douglas and Dr J. D. Spillane. Dr Douglas intends to work at the University of Minnesota and Dr Spillane at Columbia University.

International Faculty of Sciences

On May 31st, at 7.30 p.m. at the Gaumont British Theatre, Film House, Wardour street, London W., Dr S. Monckton Copeman, F.R.S., will give a lecture on experimental work bearing on the treatment of cancer, it will be illustrated with a film and lantern slides. Those who wish to attend should notify the hon. secretary, Hazlett House, Southampton Buildings, W.C.2.

British Association of Radiologists

The third annual general meeting of this association will be held at the British Institute of Radiology, 32 Welbeck street, London W., on Friday, June 11th, and on Saturday, June 12th. On the first day of the meeting Dr F. Herniman-Johnson will deliver the Skinner lecture on the after care of patients suffering from cancer of the breast. A paper on wave length as a factor in radiotherapy will be read by Mr C. F. Stebbing and Prof. J. M. Woodburn Morrison and Dr S. B. Adams will open a discussion on low voltage near distance X-ray therapy. On the second day the following will speak: Dr L. Lasholm (radiological experience in ventriculo-graphy), Dr H. W. A. Post (salpingography), Dr F. Rohan Williams (urography in pregnancy), Dr H. M. Worth (the use of hypoderm in the localisation of spinal tumours) and Dr M. H. Jupp (some observations on cases of suprarenal tumour).

Dr L W Dryland and Dr Josiah Walker have been appointed deputy lieutenants for the county of Northampton

London Hospital

On Tuesday July 6th at 3 p.m. Sir Kingsley Wood the Minister of Health will distribute the prizes to students of this hospital in the college library

Tuberculosis Association

The annual provincial meeting of the Tuberculosis Association will be held at the Central Library, Manchester on June 10th 11th and 12th under the presidency of Dr S Roodhouse Gloyne

Royal Eye Hospital

The clinical society of this hospital will hold a meeting on Wednesday June 2nd at 5.30 p.m. at which a number of cases will be shown and discussed. All medical practitioners are invited and further particulars may be had from the hon secretary at the hospital St George's circus, London S.E.

Demonstrations of Contraceptive Technique

On Wednesday June 2nd at 2.30 p.m. a practical demonstration of the technique of the use of a variety of contraceptive methods will be given by Mrs Marie Stopes D.Sc. and Dr Evelyn Fisher. Medical practitioners and senior students should apply for tickets to the hon secretary of the Society for Constructive Birth Control 108 Whitfield-street London W 1

Society for the Provision of Birth Control Clinics

A lecture on the theory and practice of contraception will be given to medical practitioners and medical students by Dr Greta Graff on Friday June 11th at 6 p.m. at the Walworth Women's Welfare Centre 158A East-street London S.E. Practical demonstrations will be given on Friday June 18th at 6 p.m. and at 7 p.m. further information may be had from the secretary at the clinic.

Wellcome Chemical Works Dartford

Mr Sydney Smith Ph.D. has been appointed works manager at the Dartford works of Messrs. Burroughs Wellcome and Co. in succession to Mr H. A. D. Jowett D.Sc. who met his death in a car accident last August. Dr Smith has been associated with Messrs. Burroughs Wellcome and Co. for 23 years and has made many contributions to the study of the alkaloids of ergot and the glucosides of digitalis

Fellowship of Medicine and Post Graduate Medical Association

The following all-day courses will be held during the summer months: gynaecology Chelsea Hospital for Women (June 14th to 20th); proctology St Marks Hospital (July 5th to 10th); dermatology Blackfriars Skin Hospital (July 12th to 24th afternoons only); urology All Saints Hospital (July 12th to 31st). Week-end courses will be held as follows: obstetrics City of London Maternity Hospital (June 12th and 13th); general surgery Prince of Wales General Hospital (June 19th and 20th); diseases of heart and lungs, Victoria Park Hospital (July 3rd and 4th); medicine and surgery Miller General Hospital (July 10th and 11th). Courses to be held in preparation for the M.R.C.P. examination are: clinical and pathological course at the National Temperance Hospital (8 p.m. Tuesdays and Thursdays, June 1st to 7th); course in chest diseases at the Brompton Hospital (twice weekly 5 p.m. June 7th to July 13th); course in diseases of the heart and lungs Victoria Park Hospital (Wednesdays and Fridays 6 p.m. June 9th to July 3rd); course in neurology West End Hospital for Nervous Diseases (afternoons, June 21st to July 3rd) fundus oculi demonstration 8.30 p.m. July 6th; pulmonary tuberculosis demonstration at Preston Hall July 3rd. Full particulars of all courses and demonstration can be had from the secretary of the fellowship at 1 Wimpole-street London W

The address of the Institute for the Scientific Treatment of Delinquency has been changed from 50 Grosvenor-street to 8 Portman-street London W 1

Memorial to Young and Noguchi

The government of the Gold Coast is erecting a memorial to William Alexander Young and Hideyo Noguchi who died from yellow fever in 1928 while working at the Medical Research Institute at Accra where Young was the director. In their memory a bronze tablet will shortly be placed in a room at the Institute and a small drinking fountain in front of the out patient block of the Gold Coast Hospital

International Union against Tuberculosis

The executive committee of the union has placed at the disposal of the governments and associations belonging to the union a biennial prize of a value of 2500 French francs in memory of the late Prof Léon Bernard who was founder and for fourteen years, the secretary general of the union. The prize will be awarded for the first time in 1938 to the author of an original essay on the social aspect of tuberculosis in French or in English. The essays must be typewritten or printed and must not exceed 10 000 words. They must be forwarded by a government or an association belonging to the union to the secretariat 66 Boulevard Saint Michel Paris (VIIe) not later than May 1st, 1938

International Union against Cancer

Twenty-one different countries sent delegates to a meeting of the general committee of the International Union against Cancer which took place in London over the week-end. They were entertained to luncheon on Saturday by the executive committee of the British Empire Cancer Campaign, and on Saturday evening they were invited by His Majesty's Government to a dinner at Lancaster House at which Sir Kingsley Wood presided. The chief business discussed by the delegates was the programme for the next International cancer congress, which it was decided should be held in Atlantic City in September 1939. The two official British representatives on the general committee are Dr W. Cramer and Mr Cecil Rowntree from whom any further information can be had

Society for Relief of Widows and Orphans of Medical Men

The annual general meeting of this society was held on May 19th with Mr V. Warren Low the president in the chair. During 1936 21 new members were elected, 9 died and 1 resigned; the membership on Dec 31st was 276. The total income for the year was £2392 and £2275 was distributed in relief to the 59 widows and 9 orphans in receipt of grants. This is an increase of £1000 over the previous year. Special grants, amounting to £217 10s., were made from the Brickwell fund to orphans to enable them to study for some business or professional careers. The president announced that in 1938 the society would be celebrating the 150th anniversary of its foundation. Membership of the society is limited to registered medical men who at the time of their election reside within twenty miles of Charing Cross. Further information may be had from the offices of the society 11 Chandos-street London W 1

Vacancies

Births, Marriages, and Deaths

BIRTHS

- ACRES—On May 9th at the Baptist Mission Bolobo Belgian Congo the wife of Dr Ian Acres of a son
- BEACH—On May 17th at Oxford the wife of Surg Lieut. Comdr W V Beach R N of a daughter
- COVE SMITH—On May 22nd the wife of Dr R Cove Smith of Stanhope-place W of a daughter
- KAY—On May 21st at Mill Hill, the wife of Dr James Kay, F.R.C.S. of a daughter
- McDOWALL—On May 22nd, at Emsworth Hants the wife of Dr Edward Benson McDowall of a son
- OWEN—On May 11th the wife of Mr O Langley Owen F.R.C.S. of Ross on Wye of a daughter
- PEGG—On May 16th the wife of Dr George Peggs of Chesham place W, of a daughter
- STEADMAN—On May 16th at Devonshire place W the wife of Dr Brian St J Steadman of a son
- WASS—On May 17th at Church-crescent N, the wife of Mr S H Wass F.R.C.S. of a son

DEATHS

- MARTIN—On May 21st at Churchill near Bristol Theodore Martin M.R.C.S. in his 82nd year
- MAY—On May 18th at Bath Colonel William Allan May C.B. R.A.M.C. (ret'd), aged 86
- POLAND—On May 22nd at Seal near Sevenoaks John Poland F.R.C.S. Esq

N.B.—A fee of 7s 6d is charged for the insertion of Notices of Births, Marriages and Deaths

NOTES, COMMENTS, AND ABSTRACTS

LEGAL CLINICAL AND COMMERCIAL ASPECTS OF BIRTH CONTROL

An important Bill concerned with contraception and abortion became effective in Iceland in January, 1935. Its provisions are remarkable because they impose upon doctors an actual obligation to give advice on contraception in certain conditions; also because they regard the woman's economic circumstances as forming part of the therapeutic indications for terminating pregnancy. The first sentence of the first section reads as follows:—

If a woman consults a doctor and suffers from a disease the nature of which is such that the doctor would deem it dangerous to the woman to become pregnant or to bear a child it shall be his duty to warn her in this matter and to direct her how to prevent conception. The physician shall be bound to give her the information required, but no one who is not a physician shall be allowed to give such directions. The Minister of Health shall publish, and the Chief Medical Officer shall distribute among physicians, Directions for women how to prevent pregnancy."

Section 9 ends with the following paragraph:—

When estimating how far childbirth may be likely to damage the health of a pregnant woman as mentioned under sub-section 1 hereof it may among other things be taken into consideration whether the woman has already borne many children at short intervals and a short time has passed since her last confinement also whether her domestic conditions are difficult, either on account of a large flock of children, poverty or serious ill health of other members of the family.

CONTRACEPTIVE SUCCESS AND FAILURE

Reports on the data at birth control clinics have been accumulating in the last fifteen years and a valuable precedent as to how they should be presented was set four years ago by Dr. Hannah Stone.¹ The information collected has social and medical aspects and the scientific reports should therefore give consideration to the economic status of the woman as measured by her husband's occupation and earnings to her age and religious affiliation to her previous reproductive history and her previous use of contraception. It is always found that the clinics lose touch with a proportion of patients and the exact number should be stated: the earlier in the clinic's history a patient is seen the greater is the chance of the clinic losing touch. Of the women with whom the clinic maintains touch some discontinue the method, either because it is not needed (in cases of sterilisation, menopause or death of or separation from husband) or because the method is found unacceptable. The number in each of these categories should be given. Finally a proportion of women use the method successfully; and another proportion experience failures—i.e. they have unwanted pregnancies when using the method advised by the clinic—which have been classified in various ways.

A report on 4000 cases by Dr. Ruth Robishaw² of Cleveland, Ohio, covers the six year period 1928-34 and gives much valuable information; but it is not clear on all these points. The reader is left to deduce that, of the patients seen during this period the clinic maintained touch with 2063—just over half the total; as is to be expected the proportion of women seen each year with whom the clinic maintained touch increased steadily from 1928 to 1933. Thus by 1931 it had retained contact with only 10 per cent of the cases seen in 1928; whereas it main-

tained touch with 96 per cent. of those seen in 1933. But particulars of all 4000 women are given by Dr. Robishaw in her report, so it is to be presumed that in 1917 cases the records of the women's experiences stop short when contact with them was lost, and thus do not cover the whole interval which elapsed between the date of their first attending the clinic and the year 1934 when the six year period ended.

In 8014 of the recorded cases the method advised was a combination of a diaphragm pessary and a lactic acid jelly. In the remaining 486 patients, 12 other methods were advised. Of the total of 4000 women 1700 successfully used the method which had been advised. 1363 discarded it because they found it unsatisfactory and 161 gave it up for reasons that had no connexion with its merits or demerits. One hundred and twelve women were pregnant before they began to use the method. Of 357 women who became pregnant after it had been used 331 experienced unwanted pregnancies; only 26 pregnancies appear to have been planned. The smallness of this proportion is remarkable in view of the fact that the average age of the women was between 25 and 30 and of the fact that in this country at least birth control clinics are used largely by women who want to space their children. Of the failures, 41 were unaccountable—i.e., were not attributed to defects in the appliances provided or to omissions of part of the procedure. The unaccountable failure rate of 1 per cent. over a period of about two years accords closely with the findings of previous investigations in America and in this country. Assuming a coitus rate of once a week, the risk of failure at each act works out at 1 in about 4000 provided that the method is properly carried out.

THE COMMERCIAL SIDE

In an account of the birth control industry in America Harrison Reeves³ gives some striking figures. It is said that 5 000 000 sheaths are sold daily and that 275 million dollars a year are spent upon them. But in addition to this 800 000 000 dollars are annually spent on other contraceptive appliances such as jellies, suppositories, caps, rings, and compounded prescriptions. The birth-control industry while not yet comparable in volume to the petroleum industry or to the industry in cosmetics and beauty appliances is one upon which is being increasingly focused the principles of scientific salesmanship. Thus we are told that the use of slot-machines in garages and public lavatories and of placards for advertisement are being discouraged but schemes are favoured for installing vending machines on battleships in army barracks, in police headquarters, and in country clubs.

Successful installations of this sort, says Mr. Reeves, would give class to the business, speed word of mouth advertising and break down one barrier after another. Since the author does not quote the sources from which his computations are drawn, his figures should be accepted with caution but they suggest the desirability of obtaining accurate data in this country with regard to a trade that now has a noteworthy sociological influence.

THE NUTRITIONAL POLICY OF THE LEAGUE OF NATIONS

At the twenty fifth session of the Health Committee of the League of Nations held at Geneva during the last days of April a programme was discussed and approved for the next three years. Consideration was given to the report of the Technical Commission of Nutrition set up in 1932 which held its first session in London in November of that year (see *Lancet* 1932, 2, 1431). This report has it seems created an impression not only in Europe but also overseas, thus the agenda of the Intergovernmental Conference on Rural Hygiene in the Far East includes items

¹ Hannah M. *Marriage Hygiene* Bombay November 1936 (English translation of the Act).

² Stone H. M., and Hart H. *Medical Health and Contraception: A Study of the Social and Medical Data of 2000 Patients*. The social data were published by the New Jersey Birth Control League; the medical data (by Stone) in the *Medical Journal and Record* April 1936 and May 3rd, 1937. Robishaw H. A. (1936) *Iowa J. Obstet. Gynec.* 31, 478.

³ Reeves H. *American Mercury* October 1936.

such as the composition of dietaries, the nutritive value of the principal foods, deficiency diseases and their method of investigation, all of them inspired by the Commission's report. In Chile a study of popular nutrition by Profs. Dragoni and Burnet is now in the hands of the Government. Nutritional problems will also figure prominently in the agenda of the Conference on Rural Hygiene in American Countries and in that of the European Conference on Rural Life, both of which it is presumed will be held during the mandate of the present Health Committee. It was felt at this session that the procedure adopted for the study of nutrition has produced valuable results in a comparatively short space of time and, having thus proved its worth, is not in need of modification at present. The report of the Technical Commission will thus remain the pivot of activity.

LE PLAY SOCIETY—Sir John Russell, F.R.S., of the Rothamsted Institute, Harpenden, is to lead a group of members and friends of this society to Soviet Russia in August. The visit will afford an opportunity for seeing something of what is being done in the application of science to everyday problems in Russia, particularly in regard to farming. The general geographical features of the country, its geology, vegetation and various social experiments will also be studied. This group will leave London on August 6th and will go via the Black Sea to Erivan in Soviet Armenia, returning via Moscow and Leningrad by boat to London. Finnish Lapland is to be visited by another Le Play group, who will stay for a short time on the Arctic coast. For geographers, botanists, and geologists, this presents a particularly interesting area for vacation study. The party will leave London on August 4th. Similar arrangements are being made for visits to Yugoslavia (Old Serbia), where there will be special interests for the geologist and the botanist, to Czechoslovakia, to the Dalmatian coast, and to the Outer Hebrides. Full details of these vacation visits can be had from Miss Margaret Tatton, director of the society, 58, Gordon square, London, W.C.1.

CORRIGENDUM—In the article on the Action of Trypsin on Diphtheria Toxin by Brandwijk and Tasman in our last issue, p. 1228 the reference in line 7 should be to various strains of typhoid bacteria.

Appointments

BROWN, D. G. W. M.Ch. Orth. Liverp. F.R.C.S. Edin. Orthopaedic Surgeon to the Royal Infirmary, Sunderland.
GIBSON, ROBERT M. B. Glasg. Assistant Medical Officer at the Bristol Mental Hospital, Fishponds.
GORDON, W. H. M. B. Glasg. D.O.M.S. Refractionist to the Queen Mary's Hospital for the East End.
HILDYARD, F. P. M. B. Glasg. Assistant Physician to Runwell Hospital for Nervous and Mental Disorders, Wickford, Essex.
HOPKINS, EDITH M. R.C.S. Eng. D.M.R.E. Radiologist in Charge of Diagnostic Work at the Elizabeth Garrett Anderson Hospital.
HOSFORD, JOHN, M.S. Lond., F.R.C.S. Eng. Consulting Surgeon to the Bethlem Royal Hospital, London.
HULBERT, N. G. M. B. Camb. M.R.C.P. Lond. Medical Registrar to the Royal Chest Hospital, London.
JOHNSON, J. F. F. M. B. Manch. Assistant Medical Officer at Woolley Sanatorium, Northumberland.
LEDGERMAN, M. B. Lond. Resident Medical Officer at the Radium Institute, London.
MCCARTHY, RITA, L.R.C.P. Irel. Clinical Assistant to the Ophthalmic Department, Sheffield Royal Hospital.
MILES, J. P. T. M.S. L.R.C.P. Edin. Temporary Assistant School Medical Officer and Assistant Medical Officer of Health for Exeter.
PRICE, MARGARET R. L.R.C.P. Lond. D.C.H. First Assistant in the Children's Department of the Royal Free Hospital, Savoy.
ROBERTSON, M. B. Aberd. F.R.C.S. Edin. D.L.O. Hon. Assistant Surgeon to the Ear, Nose and Throat Department of the Grosvenor General Hospital.
SMITH, C. M. M.D. Glasg. D.P.H. County Medical Officer of Health and Chief School Medical Officer for Northamptonshire.
THOMAS, A. R. B. Chir. Camb. D.M.R.E. Radiologist to the Bethlem Royal Hospital, London.
City Infectious Diseases Hospitals, Liverpool—The following appointments are announced:
HURST, MARY M. M. B. Liverp. Assistant Resident Medical Officer.
DODD, ARTHUR, M. B. Liverp. Assistant Resident Medical Officer and
CONCANNON, A. B. M. B. Liverp. Assistant Resident Medical Officer.

(From the Wards and the Diabetes Clinic, Middlesex Hospital)

THE evolution of the modern treatment of diabetes is marked by certain stepping-stones of fundamental importance. These are—

1. *Ladder diets* devised by Dr. George Graham. The introduction of gradually increasing and balanced diets after a period of initial starvation began a new epoch by which the mortality of diabetes was greatly diminished and the general welfare of the diabetic patient notably increased.

2. *Discovery of insulin*—This has enabled us to diminish the mortality of diabetes to a very low level even in cases of great severity; it has also reduced the mortality of diabetic coma which was previously 100 per cent. to a relatively low figure.

3. *Introduction of high-carbohydrate diets*—Several years ago observers in many countries discovered almost simultaneously that in severe cases of diabetes controlled by diet and insulin it often becomes possible to increase the daily ration of carbohydrate with benefit to the patient and without increase in the daily dose of insulin. It was even found that it was often possible to diminish the daily dose of insulin. This advance has been less fundamental than the others and has occasionally had the disadvantage of encouraging patients to eat unwise amounts of carbohydrate. It has however when properly employed brought increased liberty to the diabetic patient.

To these three advances must now be added a fourth in the form of certain new insulin preparations which act more slowly and over a longer period than does insulin in its original form. The parent of these insulins is the protamine insulin invented by Prof. H. C. Hagedorn of Copenhagen and marketed in this country under the name of Retard Insulin.¹ The other new insulin marketed in Great Britain by a group of British chemical firms is known as Protamine Insulin (with Zinc) Suspension;² its composition may broadly be described as being Hagedorn's protamine insulin with minute amounts of zinc added to it.

A further new insulin has been widely used in North America under the name of "crystalline insulin"; this product is not at present on the British market but our observations include some made with an insulin of this type and provisionally called Zinc Crystalline Protamine Insulin.³ This composition may be described as being ordinary insulin crystallised by zinc and subsequently combined with protamine.

BASIC PRINCIPLES OF TREATMENT

Discussion of the value, and of certain disadvantages of these new insulins can be clarified by a brief recapitulation of the basic therapeutic principles which have governed the majority of physicians when treating diabetes during the last twenty-five years. At first, when the immense significance of the 'starvation' treatment and ladder diets was appreciated it was believed that if a patient with diabetes was kept constantly sugar free the pancreas was placed in a condition of rest, deterioration was checked and the possibility of regeneration secured. With the introduction of insulin attention became concentrated upon the sugar in the blood but the principle of pancreatic rest still governed treatment; it was often laid down that the optimum dose of insulin was that which would prevent hyperglycaemia at any time in the twenty-four hours. The astounding success of insulin gradually brought with it the conviction that this substance had a wider effect than mere chemical control of the sugar circulating in the blood; patients properly treated with insulin do not only cease to lose weight, and regain strength, they exhibit far wider physiological restoration as may be exemplified by the disappearance of prolonged amenorrhoea in women and the reappearance of virility in men. In fact, it becomes clear that successful insulin therapy is a true replacement therapy akin to the treatment of Addison's disease with adrenal cortical extract. It might almost be said to-day that the correct dose of insulin in any patient with diabetes is the maximum dose that can be administered without the production of unpleasant symptoms.

But recent years have taught us that certain unpleasant symptoms resulting from hypoglycaemia form a very important factor in the lives of many patients suffering from severe diabetes. We can recall the case of a medical man who set out on his morning round in a new car and remembered nothing until he awoke in a London hospital with a badly cut head to receive the news that his car had been found smashed to pieces in a quiet suburban road. We were recently asked to report on a bank clerk who had at one time attended the diabetes clinic at the Middlesex Hospital and who had just achieved notoriety by entering the manager's office in the middle of the morning where he smashed the furniture and assaulted his superior. Another bank clerk who had been perfectly controlled with insulin in 1926 consulted us again in 1932 because he found that on several days a week he tended at about 11 A.M. to throw the ledgers all over the office and then retire to sulk in the W.C. for half an hour. In children a condition of pronounced nervousness, irritability and fear is often apparent at times when the effect of a previous dose of insulin is at its maximum and almost any diabetic patient who has been on insulin for a long time will, if his confidence be secured and his very proper desire to avoid crumbling be subdued, tell his medical adviser of the dread he has of these mild hypoglycaemic attacks. The new insulins with their slower and more prolonged action hold promise of making it easier to reproduce the continuous secretion of natural insulin which we believe to be the physiological condition and to diminish this risk of frequent hypoglycaemia mild or severe which is so much dreaded by the diabetic patient.

Comparison with Ordinary Insulin

Table I sets out briefly the varieties and times of action of the insulins at present available in Great

¹ Leo made by Nordisk Monin Laboratorium Copenhagen and obtainable from Glaxo, Ltd., London.
² Allen and Hanbury Ltd., Pure Drug Co. Ltd., The British Drug Houses Ltd., Burroughs Wellcome and Co.
³ Made by Organon Laboratories, Oss, Holland.

Britain. From this it is clear that the essential difference between the various insulins lies in their rate of action. All of the new insulins here are, when used, suspensions of ordinary insulin combined with prota-

TABLE I
Types of Insulin

Type of insulin	Synonyms	Commence- ment of action	Maximum effect
Ordinary insulin	—	20-40 min	3 hrs
Insulin retard	Protamine insulin Hagedorn's insulin	1-3 hrs	6-8 hrs
Zinc insulin	Protamine insulin (with zinc) suspension	9-11 hrs	15-20 hrs
Zinc crystalline pro- tamine insulin	Protamine insulin Organon	8-12 hrs	12-20 hrs

mine, the zinc insulins containing zinc in addition. All these insulins act much more slowly than ordinary insulin, and it is believed that this is due to the fact that they remain for a long time in the subcutaneous tissues, where they are broken up and slowly absorbed into the blood stream as ordinary insulin. The zinc products are far more slowly absorbed than the pure protamine insulin. Whether there is any further distinction between the action of the English zinc protamine insulins and the Dutch crystalline protamine insulin we are not yet in a position to say with certitude. Table II sets out briefly the advantages and disadvantages of the different products. In this table it has been necessary to place all the zinc insulins together, though later observations may make it necessary to separate them as regards their effects.

TABLE II
Advantages and Disadvantages of Different Types

Type of insulin	Advantages	Disadvantages
Ordinary insulin	Constant in effect in valuable in coma available in many strengths	Transient effect, multiple doses often needed, liable to produce frequent brief hypoglycemia
Insulin retard	More prolonged effect, painless on injection controls early morning hyperglycemia, never more than two doses required daily	Effect somewhat erratic, occasional severe hypoglycemic effects bulky to administer in large doses occasional difficulty in controlling glycosuria before lunch
Zinc insulin and crystalline protamine insulin	Still more prolonged effect will often control even a severe case with one injection daily	Effect somewhat erratic may produce unexpected and very prolonged hypoglycemia bulky to administer in large doses

It remains to be said that of the new insulins, insulin retard is supplied in boxes containing five bottles of the insulin and one bottle of buffer solution, a small amount of the latter having to be added to each bottle of the insulin before it is used, the addition of the buffer throws down a precipitate and until this is done the product acts exactly as ordinary insulin. A buffer solution is also supplied with crystalline protamine insulin, but in this case the buffer is attached to each bottle of insulin in a separate chamber from which it can be mixed with the insulin before the bottle comes into use. This has the advantage of obviating an essential but not

altogether trivial measurement by the patient. The English protamine insulin (with zinc) suspension is supplied mixed as a suspension which it is claimed, remains potent for six months. Each bottle is dated and it remains to be seen whether the claim of the manufacturers that their product remains stable for so long a period is justified.

HAGEDORN'S PROTAMINE INSULIN (INSULIN RETARD)

In a previous communication two of us (Bennett and Gill 1936) reported the excellent effects obtained by means of protamine insulin in the treatment of severe diabetes in children. Further experience enables us to confirm all that was said in that paper, the children are more easily kept sugar free, often only require one daily dose of insulin, rejoice in the painlessness of the injections, and are observed to be in better health and less subject to attacks of mild hypoglycemia. We have seen no ill effects from the use of this product except that one of these children was brought into hospital in hypoglycemic coma as the result of having accidentally given his injection direct into a vein. The administration of intravenous saline with glucose quickly restored him and he was in his usual health within a few hours. It is to be

FIG 1—Comparison between ordinary insulin and protamine (retard) insulin in a normal man. In the fasting man the curves show rapid recovery from effect of ordinary insulin but protamine (retard) insulin still acting 6 hours after the injection and producing hypoglycemic attack. On a fixed diet the curves show the effect of ordinary insulin buffered by lunch but protamine insulin continues to act strongly until its action is buffered by tea.

noted that all the new products, if administered intravenously, act with the same speed and in the same degree as a corresponding dose of ordinary insulin. An attack of hypoglycemia arising in this manner will therefore be exactly similar to one arising from the result of such an accident when ordinary insulin is used. Severe hypoglycemia following the subcutaneous administration of one of the new insulins may, however, be more serious than the hypoglycemia of ordinary insulin. We have not met with such an event with protamine insulin but further reference will be made to the subject when discussing the zinc insulins.

Fig 1 illustrates the effect of protamine insulin on the blood sugar. It shows the curves of blood sugar in a normal man, in one fasting, in the other on a fixed diet, after an injection of this substance.

This effect is seen in the fasting subject after the injection of 30 units and it will be noted that at the end of a few hours the effect of the ordinary insulin has quite passed off whilst the protamine insulin is acting more and more strongly at the end of six hours. Sweating, giddiness, and general mental disturbance proclaimed the advent of pronounced hypoglycemia and glucose had to be rapidly administered to the patient, the blood sugar having now fallen to 45 mg per 100 ccm. The curves with a fixed diet show the comparative effect of the two insulins given before a series of small spaced meals. Two hours after breakfast the ordinary insulin has produced the greater effect but lunch soon counteracts this, whereas

the protamine insulin is only reaching its maximum at five hours after its first administration.

We have now been using retard insulin for many months, both for children and for serious cases of diabetes in adults. In a certain number of cases we have been able to establish stability with a single daily injection given before breakfast, but in the majority it has been necessary to give a dose at night as well, and as the effect of this second dose has almost entirely ceased by breakfast next morning when the

FIG. 2.—Comparison between ordinary insulin and protamine insulin (with zinc) suspension, the latter acting powerfully 18 hours after injection. (Normal man on a fixed diet.)

FIG. 3.—Comparison between ordinary insulin and zinc protamine crystalline insulin acting strongly 18 hours after injection. (Normal man on a fixed diet.)

morning dose has not yet begun to act it is not unusual to observe a transient glycosuria for one or two hours after breakfast. For this reason certain observers have advocated the addition of a little ordinary insulin to the morning dose, but we feel that any possible advantage of this procedure is probably outweighed by the danger of obliging a patient to employ two different brands of insulin each requiring careful measurement. It must also be noted that some of the chemists responsible for the manufacture of the new insulins stress the importance of great accuracy in the pH of the substances when used, and mixture of two products will tend to upset this. While it is perhaps doubtful whether such extreme exactness is of great importance we have no evidence that any real ill effect follows a transient hyperglycemia which is only present for a very short period after breakfast.

The following illustrative cases may be cited—

CASE 1.—Dose unchanged. Reactions abolished. Female aged 29. Severe diabetes of eleven years duration. Sugar-free on 32 units of ordinary insulin morning and 28 units evening. Frequent and rather severe hypoglycemic reactions. *Result*—Now sugar free on protamine (retard) insulin 32 and 28 units. Only two mild reactions in many weeks.

CASE 2.—Dose reduced to one a day. Male aged 36. Mild diabetes for two years. Sugar free on ordinary insulin 14 and 10 units. No reactions. *Result*—Now sugar free on one daily dose of 26 units protamine (retard) insulin.

CASE 3.—Failure to secure stabilisation. Female aged 39. Severe diabetes for eleven years. Sugar free on 30 units ordinary insulin for each of three main meals. Frequent hypoglycemic attacks. Changed to protamine (retard) insulin 40 units morning 20 units evening. *Result*—Reactions abolished but has frequent glycosuria both morning and afternoon.

CASE 4.—Morning glycosuria abolished. Male aged 37. Severe diabetes ten years. Complicated by pulmonary tuberculosis now quiescent. Constant early morning glycosuria on ordinary insulin 40 and 25 units. *Result*—Now continuously sugar free on protamine (retard) insulin 41 and 30 units. *Comment*—The pulmonary complication made it important to secure complete control

in this case; it is however to be noted that with active pulmonary tuberculosis and with varying and very low tolerance, ordinary insulin with its rapid and constant action, is to be preferred to the slower insulins.

CASE 5.—Constant glycosuria abolished. Total dosage reduced. Male aged 66. Severe diabetes five years. Glycosuria never properly controlled on ordinary insulin 40 and 30 units. Occasional hypoglycemic reactions. *Result*—Now continuously sugar free on protamine (retard) insulin 38 and 20 units. Occasional slight hypoglycemia.

PROTAMINE INSULIN (WITH ZINC) SUSPENSION AND ZINC CRYSTALLINE INSULIN

Both these insulins act more slowly and for a longer period than does protamine insulin (retard). Figs 2 and 3 show the effect of an injection of 30 units of these insulins on the blood-sugar of normal individuals taking four fixed meals. It will be seen that the normal increase in blood-sugar is converted into a sharp decline which begins to be apparent only after eight hours and is approaching its maximum at about eighteen hours after the administration of the insulin. Owing to this extreme delay it is often possible to achieve stability even in severe cases of diabetes by employing a single daily dose of one of these substances. The following are illustrative cases—

CASE 6.—Incipient coma stabilised with a single daily dose. Female aged 18. Severe diabetes, two months duration. Admitted to hospital in incipient coma relieved by massive doses of ordinary insulin. She was placed on a ladder diet and gradually built up to 120 C 100 P 160 F discharged on this diet with 20 units of protamine insulin (with zinc) suspension before breakfast. *Result*—She has remained well and stable for two months.

CASE 7.—Heavy ketosis stabilised with single small evening dose. Female aged 11. Admitted with heavy ketosis and uncontrolled glycosuria. Six weeks history. Controlled with ordinary insulin. Gradually built up on ladder diet with substitution of protamine insulin (with zinc) suspension. After fourteen days in the ward she

FIG. 4.—Blood sugar observations from Case 1 taken when stability was first achieved.

FIG. 5.—Blood-sugar curves from a case somewhat similar to Case 8. Female aged 53. Zinc protamine crystalline insulin 40 units given at 9 P.M.—i.e. two hours after supper. Only fair control of blood sugar and total daily carbohydrate low (60 g). Distribution of carbohydrate; breakfast 35 per cent.; lunch 35 per cent.; tea 20 per cent.; supper 10 per cent.

was sugar free and symptomless on a single evening (9 P.M.) injection of 40 units (Fig 4). During the next week this dose was reduced to 32 units and the patient was discharged from ward. *Result*—Now attending out patients and dose is only 16 units. There have been three slight reactions at about 2 A.M.

But against apparently brilliant successes of this kind must be set a number where this is qualified by the necessity to employ more than one type of insulin.

CASE 8.—Stability on two doses of ordinary insulin failure to control with single dose of zinc insulin. Female aged 65. Severe diabetes of two years duration. Sugar free on 18 units of ordinary insulin night and morning

but subject to occasional severe hypoglycæmic attacks when taking much exercise in the mornings. Very desirous to get on to a single dose of insulin. Three weeks' careful treatment in hospital failed to achieve this but at the present time she is well on 36 units of protamine insulin (with zinc) suspension, given every evening at 8.30 P.M., on this she usually shows glycosuria between 10 A.M. and 1 P.M., which can be controlled by giving 6-10 units of ordinary insulin before breakfast. It is felt that the present position is probably preferable to the previous situation, because this patient is not very intelligent and was irregular in her meals and times of administration of ordinary insulin, there is now much less risk of hypoglycæmia and she has greater liberty in that the exact hour of the evening dose does not very much matter, it remains to be seen whether it is necessary for her to take the morning dose of insulin.

Risks of Hypoglycæmia

The risks of severe hypoglycæmia owing to cumulative or to delayed effect must be borne carefully in mind. When a patient on one of the very slow insulins develops hypoglycæmia, it is apt to appear only when the blood sugar has fallen to a very low level. With ordinary insulin a hypoglycæmic attack is the result of a sharp and rapid fall in the blood sugar level, with zinc insulins the advent of hypoglycæmia is so gradual that it sometimes produces symptoms only when the blood sugar has reached a dangerously low level. Further, it must be noted that hypoglycæmia with ordinary insulin tends to be a transient phenomenon from which the patient often emerges without special treatment, and is susceptible to rapid correction by an injection of adrenaline or the administration of a little glucose. With the zinc insulins, on the other hand, hypoglycæmia will tend to be prolonged and treatment may have to be continued over several hours before safety is re-established.

CASE 9—Severe hypoglycæmia threatening life. Female aged 23. Severe diabetes for three years, stabilised and well on ordinary insulin 25 units morning, 10 units evening. Twelve months ago married, neglected her diet and omitted evening insulin. Recently admitted to the Middlesex Hospital, pregnant three months, incipient coma and uncontrolled diabetes. She became practically stable with occasional positive urine tests on 1750 calories, including 100 C, with 66 units zinc crystalline insulin at 6 A.M. One slight hypoglycæmic attack at 11 A.M. (blood sugar 68) on 70 units. On 66 units there were no signs of hypoglycæmia until she had been taking this dose for seven days, on the seventh day she was given her 66 units at 6 A.M. and at her usual meals, twenty-two hours later, at 3.30 A.M., a night nurse reported that she was noisy and incoherent and disturbing the ward. The night nurse erroneously interpreted this as hysteria, and half an hour later she was quiet because of deep coma and was found to be cold and almost pulseless. Adrenaline was administered without effect and 10 grammes of glucose given intravenously, she became partly conscious and vomited, glucose was administered by mouth, but vomiting continued and the patient was dangerously ill until 5.30 A.M., when recovery gradually became complete. The blood sugar at 3.30 A.M. was 38 mg per 100 c.c.

The patient is now being treated with protamine insulin (retard), and is approaching stability on 16 units in the morning and 22 in the evening.

This case illustrates the potential dangers of the new insulins. We are strongly of opinion that great caution must be observed in their use when a dose exceeding about 30 units is required. When protamine insulin (with zinc) suspension was first put on the market one of us (T. I. B.) wrote a warning in the medical press, and subsequent experience convinces us that this warning was more than justified. A death from hypoglycæmia after the administration of a large dose of one of these insulins has occurred in

Great Britain, and although we have no personal experience of such a catastrophe the case recorded above was one causing great anxiety for some hours.

CASE 10—Severe diabetes controlled with single injection of 88 units of zinc insulin, treatment changed on account of danger. Female aged 17. Severe diabetes of 18 months' duration. On ordinary insulin 32 and 28 units showed variable glycosuria with frequent hypoglycæmic reactions. On protamine insulin (retard), 40 and 32 units, reactions were abolished but glycosuria constant. Next on 38 units of ordinary insulin in the morning and 36 of protamine insulin (retard) in the evening she was sugar free but still had rather frequent hypoglycæmic attacks. She dreaded multiple injections. She was re-stabilised on zinc protamine crystalline insulin, 88 units before breakfast. Only very small hypoglycæmic reactions occurred, usually in early morning before breakfast. Blood sugar estimations showed constant hyperglycæmia without glycosuria (Fig. 6). Single doses were abandoned on account of potential danger.

FIG. 6.—Severe diabetic with high renal threshold sugar free on one injection of 88 units of zinc protamine crystalline insulin.

Result.—Now sugar free and without hypoglycæmic attacks on 32 units of ordinary insulin before breakfast and 60 units of zinc protamine crystalline insulin before tea. This patient is being kept under very careful observation.

Psychology of the Patient and its Bearing on Treatment

Patients with diabetes mellitus fall into two broad but important classes—young diabetics in whom diabetes is the predominant feature of the situation and is severe, and middle-aged or elderly diabetics in whom the disease is complicated by the presence of arterial degeneration and in whom this latter feature is usually the dominating factor, the diabetes being easy to control. In both these classes psychology plays an important part in that the patient is the victim of an incurable disease that, can almost invariably be kept under control, provided that the patient has the intelligence and knowledge necessary for proper collaboration with his medical attendant. But the knowledge that the disease is incurable and that the patient is obliged to exercise perpetual discretion concerning diet is a heavy handicap, and until discipline has merged into habit this must have a depressing effect. A further psychological burden is imposed upon the diabetic patient by the well meant advice which he or she is constantly receiving from friends, who advocate changes of diet, patent foods, changes of medical attendant, and other things which are so easily urged upon someone other than one's self.

The introduction of a series of new insulins may prove a curse to a large number of diabetics who are at present being successfully treated without the use of these innovations. It must be clearly stated that the diabetic patient who has for some time been maintained in excellent health, without alarming variations in weight, and without much glycosuria or attacks of hypoglycæmia, should be advised to keep to his present treatment. The new insulins offer him no great advantage. When, on the other hand, such a patient finds the administration of multiple doses a serious burden, or when he has been subject to frequent hypoglycæmic attacks, the substitution of one of the slower insulins may prove to be a very real boon.

It must not be assumed, however, that it is a simple matter to change a patient over to one of the slower

insulin In milder cases where the total daily dose of ordinary insulin does not exceed 30 or 40 units it can often be achieved in the out-patients department without great difficulty but when the case is more severe the change must be carried out in a hospital or nursing home with most careful control of the diet and daily observations of the urine. When stabilisation is accomplished or approaching great care should be taken to see that the patient is taking plenty of exercise and a few estimations of the blood sugar specimens being secured at an appropriate time after the administration of the insulin should be made in order to be sure that masked hypoglycemia is not present.

In cases where an evening dose of zinc insulin renders the patient sugar free except for a brief period after breakfast it is often easy to control the morning specimen by a small injection of ordinary insulin but we are not satisfied that such a patient has derived real benefit because he is still receiving two injections daily and carries the risks inherent in the employment of two very different substances.

A survey of recent publications dealing with the treatment of diabetes reveals the interesting fact that many American observers have joined their British colleagues in believing that the successful treatment of diabetes must be simple. Complicated diets and the employment of more than one type of insulin in any patient are the antithesis of simplicity and we remain convinced that the requirements of the diabetic patient cannot be met by a complex treatment.

Conclusions

(1) Extensive clinical trial has now been made with protamine insulin (retard) and protamine insulin (with zinc) suspension. Experimental trial has been made with zinc crystalline insulin.

(2) These observations confirm the slower action of the new insulins as compared with ordinary insulin the maximum effect of protamine insulin being usually 6 hours after administration whilst that of

the zinc preparations including the crystalline product is often about 18 hours.

(3) The effect of the zinc insulins wears off completely in 18-24 hours. We are unable to confirm the suggestion that cumulative effects may occur—i.e. the prolongation of action beyond 24 hours (Fig 7).

(4) It is often possible to reduce the number of daily injections of insulin from multiple doses to a single dose when these slower products are employed.

(5) The protracted action of the new products carries with it the danger of prolonged hypoglycemia unless great care is observed.

(6) It is unwise in the present state of knowledge to substitute one of the new insulins for ordinary insulin unless there is valid objection to multiple doses

or frequent tendency to hypoglycemic attacks owing to the too rapid effect of ordinary insulin.

(7) The new insulins owing to variation in the rate of absorption or other causes tend to vary in their effects from day to day, and even if this variation is not of cardinal importance it is liable to have a bad psychological effect on the patient.

(8) At the present time in cases where it is desirable to employ one of the slower insulins protamine insulin (retard) is probably the safest preparation available.

Our thanks are due to our colleagues in the Courtauld Institute of Biochemistry for blood-sugar analyses here recorded. We also wish to thank the manufacturers of Leo Insulin and the proprietors of the Organon Laboratories for supplying us with insulin for experimental purposes. We would further acknowledge the constant help we have received in our work from Miss V. Scott Carmichael, the lady dietitian to the Middlesex Hospital.

PERICARDIAL RESECTION FOR CONSTRICTIVE PERICARDITIS

REPORT OF A CASE APPARENTLY CURED

By ROBIN PILCHER, M.S. Lond. F.R.C.S. Eng.
FIRST ASSISTANT IN THE SURGICAL UNIT UNIVERSITY COLLEGE HOSPITAL

(WITH ILLUSTRATIONS ON PLATE)

Churchill in 1920 collected 36 cases of pericardial resection for constrictive pericarditis, and added one of his own. More recently (1936) he has published 9 others. Paul White (1935) published a full account of the disease in his St. Cyres lecture, giving clinical details of some of the cases operated on by Churchill. Most of Churchill's collected cases came from Gormany notably those reported by Volhard, Schmieden and Fischer. In 18 of the 36 the result was excellent, in 4 there was transitory improvement, in 2 there was no improvement, and in 7 the operation was fatal. In the remaining 5 the operation was not completed. Among Churchill's own 10 cases there were 6 cures and 1 death the remaining 3 showing marked improvement. In the discussion on Churchill's later paper Blalock reported 8 operations with 3 cures, 2 improvements and 3 deaths. Other surgeons in America have reported single cases some successful some not. The only case reported in this country which I have found is that of Roberts and Wilson (1936). The absence of others suggests that either the disease is not being diagnosed or the value of surgery is not recognized. The results that have been published show that about half the patients are cured. This is at least encouraging in view of the severity of the disease and the magnitude of the operation.

The following is an account of a case in which, as in others on record diagnosis and treatment were long delayed. That operation should have succeeded completely some seven years after the onset of ascites seems to show that the very long period during which its activity was severely restricted had left the heart undamaged.

FIG. 7.—Repeated blood sugar observations on a normal man on a fixed diet before and after injection of 30 units of zinc protamine crystalline insulin showing return of blood sugar to its pre-injection level in about 24 hours.

suggestion that cumulative effects may occur—i.e. the prolongation of action beyond 24 hours (Fig 7).

(4) It is often possible to reduce the number of daily injections of insulin from multiple doses to a single dose when these slower products are employed.

(5) The protracted action of the new products carries with it the danger of prolonged hypoglycemia unless great care is observed.

(6) It is unwise in the present state of knowledge to substitute one of the new insulins for ordinary insulin unless there is valid objection to multiple doses

HISTORY OF ILLNESS

The patient, a female, was first admitted to University College Hospital in September, 1929. She was then aged 13 and gave a history of progressive enlargement of the abdomen for three months. There was no preceding illness and no other symptoms except slight discomfort from the swelling. She had had measles at the age of 8 and whooping cough at the age of 6, neither illness being attended by any complications. She had never had rheumatic fever or chorea; there was no family history of tuberculosis.

At the time of her first admission she was a normally developed, well nourished girl, 7 st in weight. The abdomen was distended with fluid, the girth 2 in above the umbilicus being 34.5 in. The liver was enlarged to three fingers-width below the costal margin, its surface being smooth. The spleen could not be felt. Distended veins were noted in the flanks and axillæ. Nothing abnormal was found on clinical examination of the heart. Percussion note was impaired and breath sounds weak at both bases. There was no oedema of the legs or face. The blood count was normal and the Wassermann reaction negative. The radiologist reported that both sides of the diaphragm were high, appearing to compress the heart, and there were increased shadows through both lung fields. Abdominal paracentesis yielded 10 pints of clear brown fluid which contained leucocytes, lymphocytes, and endothelial cells and was sterile on culture. A guinea pig was inoculated with the fluid and six weeks later showed no evidence of tuberculosis. Paracentesis was repeated after four weeks, 8 pints being withdrawn. During her stay in hospital of 107 days the temperature varied from 97° to 99° F, the average being subnormal. The pulse rate at first varied from 90 to 100, but later fell to 80 to 90. The blood pressure varied between 100 and 120 (systolic). The daily output of urine varied from 16 to 56 oz, but was seldom more than 30 oz. No diuretics were given. Blood and albumin were found on admission, but subsequently disappeared. The blood-urea was 14 mg per 100 c.c.m. The diagnosis made at this time was cirrhosis of the liver, and at the time of her discharge the patient was much relieved.

The subsequent history of the patient is one of repeated admission to hospital until September, 1935, when the diagnosis of constrictive pericarditis was made by Dr L. P. E. Laurent. Some idea of her disability may be gained from the following facts. During six years she had been admitted to hospital thirty times, spending in all nearly three years there. She has been tapped forty-two times, a total of 402 pints of fluid having been withdrawn. The maximum girth attained was 40 in. The following observations are extracts from the notes made during her various periods in hospital.

In May, 1929 the tip of the spleen was palpable and remained so, no progressive enlargement was observed.

In October, 1930, the legs began to swell. Subsequently there was a variable amount of oedema sometimes so much that the knees could hardly be flexed.

In January, 1932, there was said to be no pulsation in the cervical veins. Previous observations on this point are not recorded.

In June, 1933 omentopexy was performed. At operation the liver edge was felt to be smooth and there was some thickening of the root of the mesentery. A small umbilical hernia was present at this time.

In December, 1933 the swelling of the legs was less troublesome, but repeated abdominal paracentesis was still necessary.

In November, 1934, venous pulsation was observed in the neck to 7 cm. above the manubrium.

In January, 1935 the umbilical hernia was repaired. The site of the omentopexy was examined and the omentum was found to be atrophic, the adhesions consisting of a few strands only about $\frac{1}{2}$ in in diameter. During this admission the urine output was recorded over a long period. A

tendency to diminish had been noted on previous admissions. During 98 days the lowest daily output recorded was 3 oz, the highest 28 oz. Urea, 6 grammes three times a day, made no appreciable difference.

In September, 1935, the patient complained that in addition to her previous symptoms her eyelids were puffy in the morning. X-ray examination of the chest was repeated and the radiologist reported as follows: "Diaphragmatic movements free, diaphragm high on both sides, costophrenic angles clear. Increase in transverse diameter of heart, perhaps due to high diaphragm. Right supracardiac shadow increased. Normal pulsation. Some increase in vascular markings in lung fields. Large calcified plaque on left side near left border of cardiac shadow, 'calcification in pericardium' (Fig I on Plate). Subsequently it was shown in oblique radiograms that the calcification surrounded the heart in the form of a ring (Fig II on Plate). An electrocardiogram showed inversion of T wave in lead 3 but was otherwise normal. The diagnosis of constrictive pericarditis having been made operation was advised, but was postponed on account of respiratory infection at the suggestion of Dr J. W. McNee, under whose care the patient then was.

At the time of the patient's transfer to the Surgical Unit the following observations were made:

She was a well developed healthy looking girl aged 20, 5 ft 1 in. in height, and 9 st 1 lb in weight. The maximum circumference of the abdomen was 30½ in, this and the weight being measured shortly after paracentesis. There was no oedema of the face, legs, or sacrum, but the abdomen was distended and contained free fluid. The liver was palpable three fingers-width below the costal margin. It was smooth and did not pulsate. There was no recurrence of umbilical hernia. No apex beat was palpable, but there was systolic retraction of the precordium, with a sharp diastolic recoil. The left limit of cardiac dullness was 7.5 cm from the midline in the fifth space, the right limit was in the midline. The heart sounds were normal and no adventitious sounds were heard. There was distension and pulsation of the veins of the neck to the level of the angle of the mandible when the patient was sitting upright in bed. The pulse was regular in rate, its volume diminished on inspiration. The pulse rate varied from 80 to 95. Since the first admission the rate had always been a little above normal. The daily output of urine was still low.

OPERATION

Pericardial resection was performed on Jan 7th, 1936.

Anæsthetic, intratracheal nitrous oxide oxygen and ether. Incision T shaped (see Fig III). The sternum was divided transversely at the second intercostal space and the lower part was split longitudinally, the xiphisternum being excised. The second intercostal space was opened on either side of the sternum as far as the internal mammary vessels. The two sides of the sternum were retracted and a few adhesions between the pericardium and the chest wall were divided. The pleuræ were stripped from the pericardium without much difficulty, the left being opened by a small tear which was sutured forthwith. The surface of the pericardium was white and glistening except where adhesions to the pleura and chest wall had been divided. The pericardium appeared thick and inelastic and many calcified plaques were palpable, the largest being round the base of the heart.

The pericardium was opened anteriorly and a plane of cleavage between the visceral and parietal layers was easily found. Stripping in this plane was carried over the left border of the heart and then to the right, then up to the base, and finally round the apex on to the posterior surface. As soon as the pericardium was widely opened the heart began to fill better and bulged through the opening. The constricting effect of the pericardium was shown by a few fibrous bands left after the main stripping. These

made deep furrows in the bulging heart which expanded still further after their removal. At the base of the heart there was a dense ring of calcified material closely adherent to the auricles. On the right side this ring was severed and a segment about 1 cm square was excised. On the left side the pericardium was stripped to a higher level and another segment of the calcified ring about 2.5×1 cm was excised piecemeal. Access to the base of the heart was a little difficult and was obtained by traction on the reflected flap of pericardium which was not cut away until the stripping at the base had been carried as far as seemed safe. The greater part of the calcified ring was left but two complete gaps were made in it one on each side. The inferior caval opening was next exposed and all adhesions round it divided. A sickle-shaped band running backwards from the front of the heart to the diaphragm appeared to pull the caval opening forward. This was divided and partly excised. There was calcification round the orifice apparently in the wall of the vein itself and it was thought unwise to attempt its removal. Stripping was next continued round the apex and posterior surface of the heart until the ventricles were quite free. Two strong bands fixed the apex to the diaphragm. On the posterior aspect could be felt the continuation of the calcified ring in which two gaps had been made anteriorly. Only the anterior part of the pericardium was actually excised.

At no time did the procedure appear to embarrass the heart even when strong downward traction was made to obtain access to the base. The pericardium was washed out with saline and the wound closed with drainage at the lower end and the two halves of the sternum being held together with encircling sutures of catgut passing through the intercostal spaces. The operation lasted $2\frac{1}{2}$ hours, and at the end the pulse was 108 regular and of good volume.

The largest piece of excised pericardium is shown in Fig. IV. It was in places as much as 5 mm thick. Microscopic examination showed fibrosis and calcification, but no evidence of tuberculosis.

POST-OPERATIVE COURSE

The patient recovered rapidly from the operation. The tube was removed after 24 hours. The wound was painful for several days pain being aggravated by movements of the divided sternum. A week after operation there was observed a strong diffuse systolic impulse in the precordium the divided sternum allowing more movement than normal. No spontaneous diuresis occurred and the distension of the abdomen remained unchanged. For six weeks the daily output of urine only once exceeded 20 oz. On Jan. 23rd 1936 para-centesis was performed 17 pints being withdrawn. This was repeated on Feb. 4th 0½ pints being withdrawn. On Feb. 10th in view of the continued low urinary excretion 6 grains of Theocin was given and this dose was repeated on three succeeding days. There followed a marked increase in excretion. Administration of theocin was therefore repeated and continued until nine weekly courses had been given.

Para-centesis was performed for the last time on March 31st, 2 pints only being withdrawn. The girl was now 33½ in. A light rubber belt was fitted and the patient was discharged on April 17th 1936 since when she has remained well and able to work.

Her girl remains fairly constant being 32½ in. on March 1st 1937. Her weight at this time was 9 st. As Fig. III shows there is redundancy of the skin of the abdomen and irregularity due to the scars of the previous operations. At the present time a year after operation there has been no recurrence of abdominal distension or oedema of the feet. The manubrium and body of the sternum have not united being separated by a gap of about 1 cm. Free movement occurs at this point with respiration and with the heart beat. The two halves of the sternum are also apparently ununited and are slightly depressed in the midline. The precordium moves with the heart beat as if it were floating on the heart the upper

part coming forward in diastole the lower in systole. A feeble venous pulsation is visible in the neck to 2 cm above the manubrium when the patient is sitting upright but the veins are not visibly distended. The blood pressure is 140 systolic, 60 diastolic. There are many previous observations on the blood pressure but it is doubtful whether they are reliable. The highest pressure recorded before operation was 128 the average being about 110.

FIG. III.—Patient after operation showing scar of the incision for pericardial resection.

Further X ray examinations have been made since operation. On Feb. 26th 1936 there was little change, except that the breach in the ring of calcification was visible. The diaphragm was still elevated. On Sept. 10th the diaphragm was one space lower on each side the heart shadow being correspondingly increased in vertical diameter and slightly diminished in transverse diameter (Fig. V on Plate). On Feb. 1st 1937 no further change was apparent, and there has been no visible increase in the calcification.

COMMENTARY

In spite of the long period during which severe symptoms were present in this case operation has given the patient complete relief. It has been thought that in long standing cases the heart might suffer from the extra strain suddenly thrown on it by increased filling in diastole following removal of the pericardial constriction. No evidence of this has appeared in any case.

With regard to operative exposure of the heart there is a difference of opinion as to the best approach. Churchill and Schmieden (1926) both recommend resection of anterior ends of ribs, costal cartilages, and part of the sternum on the left side. The sternum splitting method has been little used and the American surgeons are disposed to reject it as apt to cause shock. Beck and Griswold (1930) from an experimental study of constrictive pericarditis in dogs concluded that exposure and liberation of the inferior caval opening is very important and in a case which they reported expressed dissatisfaction with the left-sided exposure. Should there be extensive extrapericardial adhesions a rib resection over the heart might be of value as in the Brauer operation but for actual exposure of the heart the sternum splitting method seems more satisfactory. A possible objection to this method is suggested by the depression of the sternum that has recently developed in my case. In the discussion on Beck and Griswold a paper Alexander reported two cases in which depression of the sternum following injury was associated with severe pain and dyspnoea which he attributed

to pressure on the heart. Both were relieved by operation, in one the sternum being elevated, in the other partly excised.

The removal of the constricting pericardium presented no great difficulty except at the base of the heart and round the inferior caval opening, where there was calcification. As recommended by Schmieden

FIG IV—Largest piece of pericardium excised at operation (cm scale)

the left ventricle was cleared first. He states that liberation of the right before the left may result in a sudden overburdening of the former, and he attributed one operative death in his series to this accident. Some disappointment was felt at the failure to deal with the calcified plaques round the base of the heart and the inferior caval opening, but the danger of tearing the heart seemed too great if more were attempted. It was clear, moreover, that liberation of the ventricles had already increased the filling of the heart and it was therefore possible that in spite of the calcification there was no serious constriction of the venous inlets. It must always be difficult to decide how much liberation of the heart is necessary to give relief. Lillenthal (1930) reported a case in which he was unable to strip the pericardium and did little more than make two incisions into it, one of which entered an auricle. In spite of this limited procedure the patient was relieved.

After operation further disappointment was felt at the persistence of ascites. There was no spontaneous diuresis such as occurred in the six successful cases reported by Paul White, and it was several weeks before the benefit of the operation was apparent. Schmieden mentions the difficulty that may occur in ridding the patient of the excess of fluid, especially from oedematous lower limbs. Theocin appeared to give the necessary stimulus in this case, and after its administration only one small paracentesis was necessary. Since her discharge from hospital the patient has had no treatment.

The important factor in this case seems to have been the constriction of the ventricles by the thickened pericardium preventing adequate filling of the heart. The band holding the heart down to the diaphragm may have narrowed the inferior caval opening by distortion. The persistence of calcification round the caval opening and the base of the heart does not seem to have detracted from the value of the operation.

CYSTS OF THE NASOPALATINE CANAL

By C BOWDLER HENRY, MRCS Eng, L.D.S.
DENTAL SURGEON AND LECTURER IN ORAL SURGERY AT THE
ROYAL DENTAL HOSPITAL, LONDON

(WITH ILLUSTRATIONS ON PLATE)

Synonyms—Median Anterior Maxillary Cyst
Supernumerary Paranasal Sinus

ROUTINE skiagraphic examination of the teeth has brought to light the prevalence of cystic enlargement of epithelial remnants in the nasopalatine canal. For the most part, unless they become infected, these cysts are symptomless, for they cause no local pain and only occasionally become large enough to bulge through the surface of the bone. The aetiology is unknown. They are commonly seen in apparently healthy mouths, and they are distinct from dental cysts originating from the epithelial rests in the periodontal membranes of the incisor teeth, with which in fact they have no connexion.

INCIDENCE

Although these cysts are seldom recorded they are not uncommon. Mayer, who in 1914 first reported one of them, subsequently (1931) dissected 600 cadavers and found an incidence of 1 in 60, and in a skiagraphic study of living adults found 1 in 100. It is probable that the cysts are often seen but not recognised, especially when small. Their main importance lies in the risk of subsequent infection, when they cause both pain and focal toxæmia, or in misdiagnosis resulting in needless extraction of perfectly sound central incisor teeth. When small, they may be overlooked entirely, or may be mistaken for merely large anterior palatine fossæ. Their pathogenic importance—if any—when uncontaminated has not been assessed.

MORBID ANATOMY AND HISTOLOGY

In their simplest form these cysts appear in the skiagram as ovoid or spheroidal cavities in the bone, above and between the apices of the central incisor teeth, which are often overlapped by the shadow (Figs I and II). Commonly, extension occurs on either side of the median line so that a characteristic bilobed appearance is produced (Fig III), or sometimes the cyst may be located upon one side only, or two separate cysts may develop side by side. The outline of the bony cavity is always clearly defined. The fibrous wall consists of loose connective tissue lined with epithelium which may be squamous, transitional, or ciliated columnar.

Kronfeld (1933) described an early cyst in the edentulous jaw of an adult cadaver. Sections showed the anterior palatine canal filled with a large mass of stratified epithelium which was solid except for a central part where cystic degeneration had occurred. He also illustrates histological sections of a larger cyst.

Histological sections are illustrated by Stafne, Austin, and Gardner (1936), who suggest that the type of epithelial lining depends upon whether the cyst arises from

(Continued from previous column)

the nasal or stomal epithelium. These writers discuss the daughter cysts, first noted by Congdon (1920) containing mucoid material and found in the wall of the larger cyst, and they describe mucous glands. The nasopalatine blood vessels and nerves were also seen within the connective tissue wall.

SIGNS AND SYMPTOMS

When the cyst is large attention may be called to the area by swelling on the palate behind the front teeth, or on the gum high up over the incisor teeth and deep to the attachment of the frenum labii. The protuberance is smooth rounded painless and hard unless there has been absorption of the bone covering when typical springy fluctuation may be elicited. Sometimes the cysts erode through both the palatal and the labial plates of bone and the impulse of palpation may be felt across from labial to palatal. Sometimes the patients detect some slight chronic discharge. In these circumstances examination of the dried surface of the palate with a magnifying mirror and a fine dental probe may reveal the fistula (Fig IV) but the orifices of those which I have seen have been capillary and only traced with difficulty. Growth is slow and patients may be unaware of the swelling until an artificial denture is fitted and causes discomfort or blocks up a fistula so that tension causes neuralgia referred first to the glabella region of the frontal bone and subsequently to the maxilla.

The patient whose radiogram is shown in Fig V was an edentulous female over 60. She had suffered for 10-12 years from frequent and repeated headaches which were ascribed to toxæmia originating in the gall bladder which she refused to have removed. The cycle of symptoms was typical. Without warning she would suffer rapidly increasing pain over the bridge of the nose extending up on the forehead between the supra-orbital sinuses. This would be supplemented two hours later by tenderness and eventual pain in the cyst and subsequently unless discharge occurred there would be slight pyrexia and the malaise of toxic absorption which always induced a painful neurofibrositis of the neck. The patient treated herself by fomenting the premaxillary region and establishing discharge. She refused a radical operation, but having had great relief from evacuation of the contents with a fine (lacrymal) cannula on a syringe and the instillation of acriflavine emulsion she consented to having a window made on the palate side large enough to allow permanent free drainage and permit irrigation with a dental water syringe. All her local and general symptoms disappeared. Bacteriological examination of the evacuated contents of the cyst showed a purulent specimen containing streptococci and diphtheroid bacilli. Culture grew *Streptococcus viridans* and a few diphtheroid bacilli ("L. Whitby").

OPERATIVE TREATMENT

The simplest treatment of the larger cysts is to make under Novocain a circular aperture in either the palatal or the labial wall sufficiently large for permanent drainage and for irrigation. A more satisfactory operation is radical removal which should be done from whichever aspect is most convenient. If the cyst presents on the labial surface above the central incisors the operation will naturally be done by this route but there is always a chance of injuring the nerve supply to these teeth with resulting degeneration and infection of their pulps. The teeth if conserved should be tested for vitality from time to time. If the cyst presents on the palate it should be removed by reflecting the palatal mucosa as for the extraction of a buried supernumerary tooth; this is simpler and the innervation of the central incisors is not so gravely threatened. The cyst

shells easily out of the bony chamber but is usually attached to the coria in the upper (nasal) portion of the ducts and found to have been adherent to the deep surface of the palatal integument below.

THE SIGNIFICANCE OF THE ANGINAL SYNDROME IN ACUTE SPONTANEOUS PNEUMOMEDIASTINUM

By ANGUS M. SCOTT, M.D. Glasg.

ASSISTANT PHYSICIAN TO THE VICTORIA INFIRMARY, GLASGOW

(WITH ILLUSTRATIONS ON PLATE)

THE solution of the anginal puzzle has attracted most clinicians at one time or another and we would agree with Allbutt (1916a) that in this secret and fell disease there is a fascination to which no physician is a stranger a fascination in its dramatic events and in the riddle to be read. That pain indistinguishable in character and intensity from true stenocardia, may occur when for any reason there is a sudden increase in mediastinal pressure is not I think widely appreciated. Wassermann (1920) noted severe stenocardia in a patient suffering from influenza pneumonia complicated by interstitial emphysema, and this after discussing the possibilities he attributed to the sudden onset of mediastino pericardial emphysema.

While spontaneous pneumothorax whether the so called benign or that secondary to hypertrophic emphysema or other disease of the lungs is a relatively common condition mediastinal emphysema must surely be rather rare. This is perhaps surprising when one considers first, the widespread use during the past decade of artificially induced pneumothorax as a therapeutic measure in chronic pulmonary disease and secondly the present-day popularity of strenuous athletics with young people of both sexes. In the cases it has been thought worth while to record here occurring as they did in young healthy adults the condition is so analogous to acute benign spontaneous pneumothorax that similar terminology—with the omission of the word benign since its benignity is at least doubtful—seems desirable.

ETIOLOGY

Mediastinal emphysema may be a complication of many diseases of the lungs. For example Keltman (1910) and Wassermann (1920) have recorded its occurrence during the influenza pandemic of 1918-1919 as a complication of broncho pneumonia and they are in general agreement about the origin and spread of the antecedent interstitial emphysema. Small areas of lung tissue which had not been involved in the pneumonic process were the seat of considerable emphysema and the strain of severe cough or urgent dyspnoea was enough to rupture the damaged and distended alveoli and to allow air to escape into the interstitial tissues and so reach the mediastinum by way of the lung root following the reflexion of the pleura and the pericardium along the great vessels.

Air may also reach the mediastinum by the extension of a subcutaneous emphysema along the endo thoracic fascia or the deep fascia at the jugulum, by the direct sucking of atmospheric air through wounds in the apertures of the thorax, by injury to the trachea and main bronchi, by openings in the mediastinal pleura so that air produced by pneumo thorax is admitted, and by extension of retro peritoneal emphysema through the crus of the diaphragm.

With this in mind, it is not surprising that mediastinal emphysema may occur in widely differing pathological conditions, and the majority of cases reported have been, as one would expect, secondary to pulmonary tuberculosis. It has also been observed as a complication of pertussis and in the new born, as the result of strangulation by the umbilical cord. It has occurred as a complication of parturition, where the condition must be due to excessive pressure on the alveolar walls while the patient is straining during full inspiration. Surgical operations on the neck and thorax, tonsillectomy and irrigations of the accessory air sinuses, and stab wounds are some of the less common causes. Congenital cystic disease of the lung, whether of the diffuse so called honey comb type or of the commoner poly- or unicystic type, is another very possible source of pneumo thorax and mediastinal emphysema.

But in the spontaneous type of which the cases here cited are examples, strenuous exertion alone may be the determining cause, and as in the cases occurring in parturient women, there may be no coexistent disease of the lungs.

SYMPTOMS AND SIGNS

Cyanosis of varying degree is usual, but if the quantity of air is small, this may not be a prominent feature. Dyspnoea or perhaps more correctly an alteration in the character of the respiration has been noted in the majority of cases, and congestion of the superficial veins of the neck will be dependent on the amount of extravasated air. The presence of subcutaneous emphysema may mask the characteristic auscultatory signs which consist of curious metallic sounds having the rhythm of pericardial friction and of similar origin to the bruit de moulin that occurs in pneumo pericardium. This sound, which has been likened to the "rattle of dried peas on taut canvas," may be audible both to patient and observer during the act of deglutition, if the air lies in contact with the oesophagus in any part of its course in the mediastinum. Finally, pain, and pain of a very distinctive character, is so striking a feature of any serious increase in mediastinal pressure from whatever cause that I think it merits a very full investigation.

My own interest in the subject was aroused when I was called on to deal with the following patient.

CASE REPORTS

A boy, aged 16, was first seen in the early hours of May 28th, 1935, complaining of excruciating pain behind the sternum and radiating down both arms, particularly the left.

Family history—There is no record of pulmonary disease in the family and there is nothing of significance in his own history. He has always enjoyed good health and has taken part in all school games.

Present illness—On the evening of May 27th he took part in a half mile foot race trial, with a view to competing at his school sports a week later. On completing the course he coughed once, dropped down, and immediately experienced a curious sensation in his chest. After resting he was able to make his way home without assistance, and retired early to bed without complaint. During the

night he was restless, could not sleep, and in the small hours of the morning, sat bolt upright in obvious distress but was unable to utter a word.

Examination—When seen a little later the boy looked desperately ill, sitting rigidly in bed, clutching the bed clothes tightly with both hands, unable to speak, and with a very anxious expression. The pulse was small and thready, his respirations were now suspended, now shallow and restrained, and he was perspiring profusely. While his face was very pale, there was evidence of acrocyanosis, and when he could relax for a second, he pointed to the upper end of the sternum as the site of his distress. His temperature was 97.0° F, the pulse rate 130, his respiratory rate very variable, ranging between 10 and 40, and his pupils were widely dilated. He was given gr 1 of morphine hypodermically, and when this had taken effect it was possible to proceed with the examination of his chest. While his whole aspect at once recalled the classical picture of angina pectoris, his clinical story was so strongly suggestive of spontaneous pneumothorax that I was surprised to find no evidence in support of this diagnosis. After the acute distress passed off, he was able to say that his pain was deep seated behind his sternum, and radiated down his arms, occasionally shooting up behind his ears producing a sense of constriction, and at times running along the ramus of the lower jaw into his teeth. He was also conscious of some movement behind his sternum, where the severe pain took origin, sometimes from its upper, sometimes from its lower end.

A provisional diagnosis of air in the mediastinum suggesting itself, he was shortly afterwards admitted to hospital, where he was examined under the fluoroscopic screen and the diagnosis confirmed. Examined in the dorsal decubitus, no abnormality could be made out, but while lying in the left lateral position, a moderately large, single, lenticular shaped bubble of air could be seen in the posterior mediastinum, and is shown clearly in Fig. I.

Progress—While in hospital the boy had several further attacks of stenocardia, none of which was quite so severe as the original, but during one of these his systolic blood pressure fell from 120 to 85 mm. Hg, and he complained of pain running down the left arm, interrupted at the elbow to resume at the wrist and continue into the left little finger. For several hours before the onset of this attack he had been conscious of some pain in the left thumb and on examination there were areas of paresthesia in this arm. He was discharged from hospital on June 15th, 1935, and was advised to avoid strenuous exercise for six months.

In March, 1936, he had a similar but milder attack after a game of football, and again in July while playing tennis he felt a sudden acute pain in his chest, but radiological examination, which was carried out 48 hours later, failed to reveal the presence of air in the thorax, and it is probable that it had been absorbed in the interval. On this third occasion the characteristic auscultatory signs were still present 24 hours after the accident but had disappeared by the following day.

For particulars and the radiogram of the second case, the clinical details of which are unfortunately lacking, I am indebted to Dr Richard Schatzka, assistant radiologist to the Massachusetts General Hospital, Boston, who has kindly consented to its publication.

A healthy youth, aged 20, collapsed at the end of a hundred mile cycle race, complaining of severe pain in his chest in the region of the sternum, but unfortunately details as to its radiation are not available. He was examined radiologically some hours after the onset and Fig. II shows the mediastinal emphysema on the left side, and considerable subcutaneous emphysema in both supraclavicular areas, with no sign of pneumo thorax, if we restrict the use of that term to denote the presence of air in the pleural cavity. The air was completely absorbed in a few days.

COMMENT

While the question of a cardiopathy did not arise in the case of the first boy, there is no doubt that the occurrence of similar symptoms in a person twenty

years older would have given rise to considerable difficulty and in this connexion it is interesting to note that Hamman (1934) dealing with the differential diagnosis of coronary occlusion cites three cases of interstitial emphysema of the lungs that came under his personal observation and where following the escape of air into the mediastinum the pain was similar in type and distribution to that seen in coronary disease.

Inspection of the lateral view of the thorax in Fig 1 shows the collection of air to be in the posterior mediastinum in close contact with the tissues surrounding the aorta, and the increased pressure must have exerted its greatest effect on these structures. The fact that the air was not distributed loosely through the tissues but remained circumscribed may have accounted for the great severity of the reaction, and in my view it seems difficult to escape the conclusion that this sudden alteration of pressure was responsible for the initiation of the anginal attack. That alteration in mediastinal pressure particularly if it be sudden may have alarming and even fatal results is well known. More than ten years ago Lord (1925) noted that death apparently due to deep emphysema had been observed in 3 instances after the induction of artificial pneumo thorax and Ballou and Francis (1929) quote a series where mediastinal emphysema as a complication of artificial pneumothorax occurred 15 times in 8 of 63 patients so that the work of these two on the consequences of variations in mediastinal pressure is of some practical importance. They conclude that the initial change in blood pressure after the inflation of a balloon in the rabbit's mediastinum is always a fall, and that some of the results of increased pressure in the mediastinum are (a) pulmonary emphysema (b) oedema of the tracheo bronchial mucous membrane, (c) pericardial effusion (d) disordered heart action and (e) acute oedema of the lungs. Normally the mediastinal pressure is round about minus 4 mm. of water and there are no noticeable changes until it reaches zero when changes do occur and progress rapidly depending on the amount of pressure and the rapidity of increase. When the pressure is raised beyond plus 35 death takes place from acute pulmonary oedema.

DISCUSSION

Many will recall with interest the lively debates of twenty years ago as to whether anginal pain was aortic or myocardial in origin. Allbutt (1916b) at great pains to prove by masterly and convincing argument that angina pectoris is a disease sui generis talks at one of his contemporaries who dares to prefer the more popular "syndrome" or symptom group concept, and accuses him of propounding the theory that a similar series of events can have dissimilar causes. He himself (1916a) finds an excuse for this reluctance to accept angina as a disease in the shifting explanations of the pathology of the anginous process and surely there is some justification for such hesitation if it be taken as proved that this dynamic procession of symptoms may result from such vastly different pathological conditions as coronary thrombosis and mediastinal emphysema. Such an admission would not necessarily imply that the mechanism responsible for the dynamic procession was different in the two conditions but would certainly suggest that it may be set in motion by very different pathological factors.

Ewart (1912) quotes a case from Perez that has evoked much comment, where the patient, an elderly phthisical subject suffering from tuberculous medi-

astinopericarditis experienced typical anginal pain, and Allbutt (1916a) mentions the remarkable case of angina recorded by Haygarth of Chester which proved on autopsy to be one of mediastinal suppurative inflammation apparently involving the base of the heart and the great vessels. Haro (1900) considered that angina was due to painful distension of the mediastinum and this to intense vasomotor constriction in very large areas elsewhere but Allbutt points out that vasomotor changes although relatively common in angina are not essential and, propounding his well known pressure tambour theory in which the suprasmoid portion of the aorta is regarded as the mainspring of the attack, he adduces valuable evidence in its support. There can be little doubt, I think, that true angina may occur in the entire absence of any pathological lesion in the coronaries and conversely gross disease in these vessels does not necessarily predicate attacks of angina. It seems reasonable to suppose therefore that they play no part in the actual mechanism of the anginal syndrome. That disturbance of their function however particularly if it be sudden—spasm or thrombosis—may set the anginal mechanism in motion seems more than probable and if so must we not assume the presence of a 'knot of exalted sensibility' somewhere in the circuit? Most physiologists are now agreed that there is an important vasosensory area in the first part of the aorta, and Spiegel and Wassermann (1926) by injecting saline into a part of the aorta that had been ligatured off were able to produce pain in dogs (as registered by movements of the animal's lower jaw) after vagal section and sympathectomy. This proof of pain as a result of stretching of the investment of the aorta is in complete accord with the views of Allbutt and Wenckebach and the former (1915a) cites a number of cases of rupture of the aorta, where the vessel coats were split asunder by dissecting hæmorrhage and where this accident was associated with intense anginal pain. Sutton and Lueth (1930) who are on the side of the coronarians state that the nerve fibres responsible for conducting the pain sensations from the heart are those fibres in the adventitia of the blood vessels or the adjacent tissues.

It seems reasonable to postulate the existence of a complex and highly specialised centre controlling the anginal mechanism when one considers the analogy of a similar control of the important lung reflexes by just such a centre or centres situated at the lung root, and of whose existence the thoracic plastic surgeon is only too well aware. Remembering the course of the sensory fibres which accompany veins as well as arteries it seems likely that this centre—or the more important station of this centre—is situated in the integuments of the aorta and that a lesser or substation may be similarly related to the pulmonary artery which might account for the dramatic results of embolism of that vessel. Further from some interesting observations of Wassermann (1931) on forced respiration and apnoea in angina it seems that there may be a very close liaison between these cardiac and respiratory control stations. Indeed according to Anrep (1930) there are some physiologists who maintain that the aorta and the carotid sinus are the chief regulators of respiration. Fortunately the vexed question of the pathway of impulses to the sensorium and their various reflex arcs does not come within the scope of this discussion.

SUMMARY

Two cases of acute spontaneous pneumomediastinum are reported and the occurrence of the anginal

syndrome in one of these is noted and discussed. A plea is put forward for a reconsideration of Allbutt's well thought out "sensitive tambour" theory of the initiation of anginal pain.

ON THE RELATIONSHIP BETWEEN THE MALE GONADS AND THE ADRENAL GLAND

By W CRAMER, Ph D Berlin, D Sc Edin,
M R C S Eng

AND

E S HORNING, M A, D Sc
BEET MEMORIAL FELLOW

(From the Imperial Cancer Research Fund, London)

(WITH ILLUSTRATIVE PLATE)

THE adrenal of the adult male mouse consists of a relatively large medulla and a relatively narrow cortex. It has been described and figured by Cramer in his book "Fever, Heat Regulation, Climate and the Thyroid Adrenal Apparatus". When adult male mice are castrated the volume of the medulla charged with adrenaline undergoes a marked diminution and a broad ring of tissue appears between the central medullary core and the cortex (Fig II on Plate). This ring of tissue when examined by the routine histological methods is seen to consist of cells which have neither the appearance of cortical cells nor of medullary cells. The appearance of this ring of tissue after castration was first described by Deane'sly and has now been confirmed by us. It is identical in appearance with the ring of tissue seen in normal young female mice and described in the literature as

boundary zone or X zone. This zone is not present in the adrenals of male mice of mixed strains. In the adrenals of female mice it gradually disappears as the animals get older.

When the male sex hormone testosterone is injected into castrated male mice the volume of the medulla increases, the X zone rapidly disappears, and the adrenal resumes the appearance of the gland seen in a normal adult male mouse (Fig I). The same result is obtained when testosterone is injected into young but sexually mature female mice, in which this zone is almost always present. This applies to intact and to spayed female mice (Fig IV). In such mice the injection of testosterone also leads rapidly to the disappearance of the boundary zone, with an increase in the volume of the medulla (Fig III). None of the anterior pituitary hormones that we have applied produces this effect which appears, therefore, to be caused by a direct action of testosterone on the adrenal gland. The oestrogenic hormones also fail to bring about a disappearance of the X zone in normal female and in spayed female mice.

The testosterone preparation used was testosterone propionate, which had been very generously put at our disposal by Messrs Schering Kahlbaum. It was injected three times weekly in doses of 1 mg dissolved in oil for periods varying from 12-28 days. The first injection was given two weeks after castration.

These observations demonstrate a close functional relationship between the adrenal gland and the male sex hormone. In the absence of the latter the number of the medullary cells fully charged with adrenaline and available for the functional activity of secreting adrenaline is greatly diminished. The X zone or boundary zone which appears after castration consists mainly of medullary cells which have temporarily been inhibited from forming adrenaline. That this is so can be demonstrated conclusively by examining the adrenal gland of castrated mice after fixation in osmic vapour. By this method the adrenaline of the medullary cells is rendered visible as osmophil granules. In the gland of a normal male mouse all the medullary cells are fully charged with adrenaline, and the medulla has a regular outline sharply delimited from the cortex by a leash of blood vessels. After castration the adrenaline granules have partly or completely disappeared from the peripheral part of the medulla. There is still a central core of medullary cells fully charged with adrenaline, but this central core is diminished in volume and its outline has become irregular. Passing outward from this there is a gradual transition from these fully charged cells to cells only partly charged with adrenaline granules, and in the peripheral part quite free from them, but even when the cells are free from

adrenaline they still show the arrangement in alveoli characteristic of the medulla. Such an alveolus may sometimes consist half of cells still containing adrenaline granules, while in the other half the cells are free from them or an alveolus of cells fully charged with adrenaline may lie like an islet among cells deprived of adrenaline. In the peripheral part of the X zone the cells are often indistinguishable from cortical cells deprived of lipoids so that the peripheral part of the X zone may consist of cortical cells. Even the leash of blood vessels which normally delimit the medulla can sometimes be seen at the peripheral end of the X zone. The same phenomenon of an ebbing away of adrenaline from the peripheral part of the medulla can be demonstrated in the adrenals of young female mice where the X zone is almost always present (Fig V). The phenomenon was described and figured in greater detail than is possible in this communication by Cramer in his book, although he did not recognise then that it was essentially a sex difference.

A number of other observers (Tamura, Howard Miller Deaneley and Whitehead) have since interpreted the X-zone or boundary zone as representing a separate anatomical entity distinct from either cortex or medulla and disappearing as the result of a process of degeneration. Grollman in his book calls it a third tissue and ascribing to it on purely speculative grounds masculinising properties has called it androgenic tissue. The rapid appearance of this zone in adult male mice after castration and its rapid disappearance after the administration of testosterone shows that this view is untenable and that the term androgenic tissue is in any case a singularly inapt misnomer.

CONCLUSION

The experiments with testosterone show that the X zone is the morphological expression of a functional change in the adrenal gland, and in so far as this functional change consists in a marked diminution in the number of cells charged with adrenaline and available for the secretion of adrenaline this functional change may logically be described as an inhibition. The action of testosterone on the adrenal gland thus affords a satisfactory explanation of the phenomenon of the X zone in normal mice. It is absent in male mice, because under the influence of testosterone the medullary cells maintain their full load of adrenaline throughout the whole extent of the medulla. The X zone is present in young female mice even when sexually mature, because in the absence of the male sex hormone the peripheral cells of the medulla do not maintain their load of adrenaline. The fact

that the X zone disappears in female mice as they grow older seems to indicate that there is an increased formation of the male sex hormone in female mice as age advances.

THE TREATMENT OF STREPTOCOCCAL INFECTIONS IN MICE WITH 4,4'-DIAMINODIPHENYLSULPHONE

By G A H BUTTLE, M.A. Camb M.R.C.S. Eng

DORA STEPHENSON Ph.D. Leeds

OF THE WELLCOME PHYSIOLOGICAL RESEARCH LABORATORIES
BECKENHAM KENT

S SMITH Ph.D. Kiel, T DEWING M.Sc. Lond.

AND

G E FOSTER, Ph.D. Lond.

OF THE WELLCOME CHEMICAL WORKS, DARTFORD

ARTUR Domagk's initial discovery (1935) of the therapeutic value of Prontosil in streptococcal infections of mice, and the further discovery by Tréfouël Nitti and Bovet (1935) that *p*-amino benzene-sulphonamide (commonly called sulphamidamide or sulphonamidamide P) was also active a number of other compounds of this series have been tested (Buttle et al. 1936 Fournéau et al. 1936 Goltsedet et al. 1936 Tréfouël et al. 1937 Gray et al. 1937) but in no case was there a striking increase in activity over sulphonamidamide.

The present communication deals with two compounds of a different chemical structure. The first 4,4'-diaminodiphenylsulphone, is considerably more active than sulphonamidamide in curing streptococcal infections of mice but is more toxic to mice; the second 4,4'-dinitrodiphenylsulphone is as active as sulphonamidamide but is less toxic. 4,4'-diaminodiphenylsulphone NH_2 ,  SO_2 ,  NH_2 , (Fromm and Wittmann 1908) occurs in very long colourless rectangular plates m.p. 176°C. It is sparingly soluble (0.01 per cent.) in water at room temperature, but more soluble (0.05 per cent.) in

All sections are of adrenal glands of mice fixed by the osmic vapour method. Figs I-IV are photomicrographs and Fig V is a camera lucida drawing. In Figs I-IV C=cortex; Z=zona reticularis; X=boundary zone or X zone; and M=medulla.

FIG I.—Section through adrenal gland of a castrated male mouse showing the disappearance of the X zone after administration of testosterone propionate.

FIG II.—Adrenal of castrated male mouse with a broad X zone.

FIG III.—Section of adrenal of a spayed female mouse illustrating complete disappearance of the X zone following treatment with testosterone.

FIG IV.—Adrenal of a spayed female mouse showing a broad X zone.

FIG V.—X zone of female mouse adrenal showing on the left the medullary core of the gland (CA) with its cells fully charged with adrenaline and on the right the inner end of the zona fasciculata (ZF) of the cortex with its cells containing lipid globules. Between them lies the broad X zone. It is composed of cells partly charged with adrenaline (C) lying next to the medullary core and of cells with large clear nuclei free from adrenaline but still arranged in alveolar formation (B). Among them there are islets of cells fully charged with adrenaline (A). Thus part of the X zone becomes completely charged with adrenaline after testosterone and belongs to the medulla. The peripheral part of the X zone in this figure consists of irregularly arranged cells free from cell inclusions (D) and it is cortical in origin.

Mice weighed 25 g

hot water 4 4'dinitrodiphenylsulphone (Fromm and Wittmann 1908) is an amorphous yellowish powder, insoluble in water

TOXICITY

Sulphanilamide is tolerated in 50 mg doses given by mouth to mice of 20 gramme weight, these doses can be repeated daily in 25 g mice infected with streptococci (Buttle et al. 1936). The 4 4'dinitrodiphenylsulphone is tolerated in 200 mg doses given by mouth, but a 400 mg dose is lethal, doses of 40 mg can be given repeatedly to infected mice. The 4 4'diaminodiphenylsulphone is tolerated in 5 mg doses given by mouth, 2 mg can be given daily to normal or infected mice, but daily doses of 5 mg kill some of the animals. The drug is slightly more toxic in infected animals.

Although the diaminosulphone is about ten times as toxic as sulphanilamide when a single dose is given to normal mice (and about twenty five times as toxic when the doses are given daily to infected animals), it is not more toxic to normal rabbits and monkeys. Single doses of 2.0 g per kg of either of the drugs produce slight symptoms in the rabbit but not in the monkey. (The dinitro compound has not yet been tried in these animals.) A single dose of 0.3 g of the diamino compound was taken by a healthy human individual and caused no symptoms, five hours after the administration of the drug, however, the blood contained a very small quantity of methaemoglobin. A monkey which had received much larger doses of the drug (1.0 g per kg) had a much larger quantity of methaemoglobin in the blood, but this was not associated with any respiratory embarrassment or other change. A similar dose of sulphanilamide when given to another monkey did not produce methaemoglobinemia.

We are indebted to Mr G. Discombe, St Bartholomew's Hospital, for demonstrating the presence of small quantities of methaemoglobin in the blood (see Discombe 1937). The urine of the individual mentioned above was examined for the presence of the sulphone using the diazo reaction with thymol. There was a considerable quantity in the 12 and the 18 hour specimens, but very little was excreted in the

first 6 hours. Blood counts were normal the day after taking the drug.

Toxic doses of these sulphones have an action on the nervous system in mice which is somewhat different from that of sulphanilamide. With the new drugs the mice appear exerted and often run continuously round their cages, if they are taken from the cages and placed on the table, they move about without any apparent purpose, sometimes running straight over the edge, when lethal doses are given, they become paralysed and have difficulty in respiration. With sulphanilamide, on the other hand, the mice rapidly become paralysed and move their limbs continuously in an incoördinate manner. The symptoms produced by the new drugs are much more persistent than with sulphanilamide, they may last for 48 hours or longer, whereas with sulphanilamide the mice either die or recover within 6 hours. Lethal doses of the new drugs cause intense dilatation of the stomach and small intestine in mice, and slight swelling of the belly may be observed in rabbits which receive large doses, but it is not great in proportion to the size of the animal. These changes are not produced by sulphanilamide.

THERAPEUTIC EFFECTS

In haemolytic streptococcal infections—Mice were infected with streptococci ("Richards") intraperitoneally and treated with the various drugs, administered orally (Buttle et al. 1936). Table I shows a comparison between the therapeutic effects of sulphanilamide and of the dinitro and diamino sulphones. The dinitrosulphone is as effective as sulphanilamide when similar doses are used. In the case of the diaminosulphone, doses of 0.4 mg are as effective as 40 mg of sulphanilamide, and doses of 0.04 mg are only slightly inferior, owing to the toxicity of the drug, however, doses of 4 mg of the sulphone do not give such good results. The second part of the Table shows that a better degree of protection is obtained against a large dose of culture with 2 mg of the diaminosulphone than with 50 mg of sulphanilamide. (Approximately 2000 mice have been used in this investigation but hitherto no more than one strain of haemolytic streptococci.)

As the diaminosulphone is not more toxic for rabbits than sulphanilamide, it would be interesting to know how the two drugs compare in therapeutic activity in this animal. Unfortunately we have not been able to obtain a Lancefield Group A strain or any human strain which is virulent for rabbits. Preliminary experiments have been done with a Group C strain P.230 which was isolated from a guinea pig epididymis by Dr Theobald Smith and was sent to us by the courtesy of Dr Homer Swift. Although the diaminosulphone is more active than sulphanilamide the difference between the drugs is not so great as in the mouse experiments. It appeared from the rabbit experiments that daily doses of 15 mg per kg of the sulphone by mouth are not quite so effective as 160 mg per kg of sulphanilamide; on the other hand doses of 160 mg per kg of the sulphone are more effective than doses of 160 mg per kg of sulphanilamide.

The bactericidal effect of the blood of a (3.1 kg) monkey (*Sileneus rhesus*) was studied at intervals after the administration of (a) 4 g of sulphanilamide and (b) 1 g of the diaminosulphone given by mouth (Table II). The rotating tube technique (Colebrook

II—hemolysis of the blood with full growth of streptococci

Controls with normal blood from another animal were put up on each occasion and the cocci grew freely from the smallest inoculum.

et al. 1936 Todd 1927) was used in these experiments. The maximum bactericidal effect was of the same order in both cases the effect of sulphanilamide however disappeared within 48 hours whereas that of the diaminosulphone which was not quite so rapid in its onset lasted for 96 hours. This experiment was repeated another monkey weighing 2.5 kg received 200 mg of each drug on two separate occasions and it was again found that the maximum bactericidal effect obtained was of the same order for the two drugs. 300 cocci were killed in 0.5 c.c. samples after treatment whereas 3 cocci grew freely in normal samples. The effect of the diaminosulphone was again more persistent than that of the sulphanilamide.

The bactericidal effect in the blood of man after the administration of the drug by mouth has not been sufficiently determined but in one experiment in which a dose of 0.3 g. was given 0.5 c.c. samples

of blood (G A II B) withdrawn six hours after the administration destroyed 400 cocci and inhibited the growth of 40 000 whereas 400 cocci grew in a specimen of blood taken before administration, and 40 cocci were destroyed.

When 0.001 per cent of the diaminosulphone was added to 0.5 c.c. quantities of monkey blood in vitro a bactericidal effect was obtained which was greater than that with sulphanilamide in equal concentrations but it was not quite so great as that with 0.01 per cent of the latter. With 0.001 per cent of the sulphone 80 cocci were completely destroyed and the growth of 800 was slightly delayed with sulphanilamide on the other hand 0.001 per cent. only delayed the growth of 8 cocci for 48 hours while 0.01 per cent delayed the growth of 800 cocci for 72 hours and destroyed 80 completely. The results with 0.01 per cent of the sulphone were slightly better than those with 0.01 per cent of the sulphanilamide.

In another experiment with human blood (N McL.) 120 000 cocci were destroyed by 0.01 per cent of the sulphone whereas with a similar concentration of sulphanilamide 12 000 were destroyed and the growth of 120 000 delayed for 48 hours. 120 grew freely in the control and 12 were destroyed.

In non-streptococcal infections.—Preliminary experiments indicate that the diaminosulphone (2 mg doses) is considerably more effective than sulphanilamide (40 mg doses) in prolonging the lives of mice infected with pneumococci but it is as yet uncertain whether mice can be completely cured. In the treatment of typhoid infections the diaminosulphone is less effective in doses of 2 mg than sulphanilamide in doses of 25 mg. These differences in therapeutic efficiency appear to be associated with the fact that a prolonged action of the drug is required for protection against pneumococcal infections in mice and a rapid action is necessary for protection against typhoid infections (Buttle et al. 1937). The diaminosulphone is also effective in staphylococcal infections.

DISCUSSION

When patients are treated with sulphanilamide it is necessary to give large doses by mouth. This is sometimes inconvenient or difficult. It would therefore be of interest if a compound could be discovered which even when given in smaller doses would be as efficient as sulphanilamide in treatment.

The results presented in this paper show that 4:4 diaminodiphenylsulphone is much more active than sulphanilamide in curing streptococcal infections of mice and that, while it is more toxic for mice than the latter compound it is not more toxic for rabbits and monkeys except that it causes methemoglobinemia more readily in the monkey. When the diaminosulphone is added directly to monkey or human blood in vitro it appears to be slightly more effective than sulphanilamide. Further when the drugs are given by mouth to normal monkeys the maximum bactericidal effects obtained in the blood are of the same order in each case although the action of the diaminosulphone is more persistent. In view of these facts it is somewhat difficult to understand why mouse infections are cured by doses of the diaminosulphone so much smaller than those required with sulphanilamide. The latter is absorbed and excreted very quickly by the mouse the concentration in the blood falls to about one tenth of its initial value in 7 hours and to one hundredth of this value in 13 hours. It seems probable therefore that there is not a uniformly high bactericidal effect. The experiment

with the monkey suggests that the bactericidal effect of the sulphone, on the other hand, is maintained. Thus persistence of the bactericidal effect may account, in part, for the difference between the drugs, but it seems unlikely that it is the only factor concerned. It is highly improbable that either the diamino- or the dinitro sulphone could give rise to *p* aminobenzenesulphonamide in the body, and their activity is of special interest since it indicates that streptococcidal activity is not confined to drugs which contain, or could easily produce, substances containing a sulphonamide group.

SUMMARY

1 4,4'-diaminodiphenylsulphone (diaminosulphone) is active in curing streptococcal infections of mice in doses of about one hundredth of those required with *p* aminobenzenesulphonamide (sulphanilamide), it is, however, twenty five times as toxic. The drug is not more toxic than sulphanilamide in normal rabbits or monkeys, except that it is more active in producing methemoglobinæmia in the latter animal.

2 The corresponding dinitro compound (dinitro sulphone) is not so toxic to mice as sulphanilamide and its antistreptococcal activity in mice is not inferior to that of the latter substance.

We have to thank Mr W H Gray for the preparation of the dinitrosulphone, Dr J W Trevan for his help and criticism, and Mr H Proom for estimating the sulphone and sulphanilamide in the specimens of urine and blood.

Note—Since the above paper was written Dr F Nititi of the Pasteur Institute, Paris, has kindly written to us saying that he has been working independently with the dinitro compound, and that his results are in general agreement with ours.

TEHDY SANATORIUM, CAMBORNE—Mrs Bolitho, wife of the lord lieutenant of Cornwall, opened a new orthopaedic unit costing £5000 at this hospital on May 19th. It provides accommodation for an eight bed ward, five double bed ward, and three single bed wards, and has been designed to give the maximum of air and sunshine. It is to be used entirely for surgical orthopaedic tuberculosis cases.

BIRTH-RATE IN SOVIET UNION—According to official reports, the birth rate in Soviet Russia is steadily increasing. Last January the number of births registered was 21.7 per cent higher than in January 1936, and in the first quarter of this year it was about 30 per cent higher than in the corresponding quarter of 1936. Of the Union republics, the Ukraine records the largest increase for this quarter—namely, 70 per cent. Up to April 1st the local authorities had effected transfers of 566 million roubles for the payment of allowances to mothers of large families. The number of mothers in the country receiving these allowances is given as 270,000.

ERYSIPELAS TREATED WITH PRONTOSIL

BY G E BREEN, M D N U I
AND

IAN TAYLOR, M B, M R C P Lond, D P H
SENIOR ASSISTANT MEDICAL OFFICERS AT THE NORTH
EASTERN FEVER HOSPITAL LONDON

EACH of the preparations of the Prontosil group has been used in the treatment of erysipelas as it appeared. Of the early publications on this subject mention may be made of the work of Mever Heine and Huguennin (1936) who treated 160 cases of erysipelas, beginning in May, 1935. They found that apart from rare exceptions a fall of temperature and local amelioration took place with impressive similitude. Eight of their cases were infants under a year, all of whom were successfully treated. Tonndorf (1936) reports 22 prompt successes with one relapse.

The route of administration of these preparations may be varied to suit individual cases. The use of the oral route has received strong support from the recent experimental work of Marshall, Emerson, and Cutting (1937) with para aminobenzenesulphonamide. These workers found that the concentration in the blood of dogs does not mount quicker or higher after subcutaneous injection than after oral administration. Absorption by the gastro intestinal tract is complete in four hours, and two or three days elapse after discontinuation before the body is free of the drug.

RESULTS

The present consecutive series consists all told of 46 cases. Of these all but 5 were examples of the facial variety. The diagnosis was made on purely clinical grounds. No bacteriological confirmation was sought or considered necessary. Prontosil in one or other form was given to 35, and various other forms of therapy to 10. All cases were in addition painted locally twice daily with a mixture of glycenn and ichthyol. In the whole series there were 2 deaths. One was a man aged 71, who was admitted in a moribund state with gangrene of the nose, cheeks, eyelids, forehead and scalp (at sight of which an attendant fainted). He was obviously beyond the reach of any therapeutic measure or agent and died within 48 hours, he is omitted from either series. The other was also a man aged 71, admitted with sharp erysipelas of the left hand and forearm, which responded promptly to treatment with Prontosil Album. Unfortunately five days after admission a cerebral hæmorrhage supervened, and death occurred within 24 hours.

An analysis of the records of the remainder of the patients is illuminating. Admittedly 10 controls are much too few for even so small a series as this one, nevertheless the evidence they afford cannot be disregarded, especially when it is considered that clinically they were the milder cases and were purposely selected for that reason. Summarised the results are as follows—

Of 35 cases treated by prontosil from admission 33 had regressed 1 had spread and 1 was stationary 48 hours later. There was one subsequent relapse. Of 10 cases not treated with prontosil 4 had regressed 5 had spread, and 1 was stationary 48 hours later. There were no relapses (Fig. 1). Of the five no prontosil cases which had spread 3 were subsequently treated with prontosil, and within 48 hours they had also regressed.

The effect on the temperature is shown by the composite graph in Fig 2 and on the pulse by the graph in Fig 3. It will be seen that the average temperature of the prontosil cases fell to normal or below in 48 hours whereas the average of the other cases remained above normal. As regards the pulse the advantage lies with the no prontosil group but it has to be remembered that they were regarded clinically as milder cases and this is reflected in the lower temperature and pulse-rate on admission.

The cases are given in age-groups in the Table. It will be noticed that of 6 cases in the 50-65 no prontosil group 3 spread while of a similar number in the prontosil group all regressed. Of 9 cases in the over 65 prontosil group none spread and only one was

FIG 1—Effect of prontosil on the progress of the disease.

FIG 2.—Average temperature chart.

FIG 3.—Average pulse-rate chart.

stationary the other 8 having subsided whereas the solitary no prontosil case in the same age group was noted as stationary.

Turning to the prontosil group as a whole a further noteworthy fact emerges. The drug was administered by mouth in all but 2 cases. Two five grain tablets of prontosil album three times daily

COMPARISON OF RESULTS

Age-group	0-5	5-15	15-30	30-50	50-65	Over 65
PRONTOSIL CASES						
Cases	2	3	8	7	6	9
Regressed	1	3	8	7	6	8
Stationary	—	—	—	—	—	1
Spread	1	—	1	—	—	—
Relapse	—	—	—	—	—	—
OTHER CASES						
Cases	—	—	3	—	6	1
Regressed	—	—	1	—	3	1
Stationary	—	—	—	—	—	—
Spread	—	—	2	—	3	—
Relapse	—	—	—	—	—	—

was the ordinary adult dose smaller doses proportionately to body weight being given to children. In two cases however—one a baby of 7 months who objected to the inclusion of the powdered tablets in his feeds, and the other an adult female of 69 who was comatose on admission and for some days later—the drug had to be administered intramuscularly in doses of 5 c.cm. The baby was the only case of spread after 48 hours recorded in the prontosil

series, and the spread was slight and of short duration the adult was the only prontosil case reported as stationary after the same period. She subsequently developed lung abscesses on both sides that on the left cleared up that on the right persisted. (A report of this case is to appear elsewhere.)

The single relapse recorded occurred in a young adult female. The attack was a moderate one and her response to treatment by tablets was so prompt that the drug was discontinued after three days. She was about to be discharged on the tenth day when the relapse occurred. This yielded so promptly to a resumption of treatment that she was actually discharged a week later. In this connexion Tonndorf cites a similar case following five days medication.

The average length of stay in hospital in the prontosil cases was 18.4 days which compares favourably with the figure of 23.8 days in the other series.

Both series were remarkably free from complications. A moderate degree of cervical adenitis was noted on admission in a number of cases. One in particular already referred to presented in addition corneal ulceration with much oedema of the lids, a severe stomatitis laryngitis and pneumonia. Pulmonary abscesses subsequently developed. There was a notable absence of toxæmia and her general condition improved so much that she was transferred to a thoracic unit for further treatment.

DISCUSSION

With the small number of cases and controls at our disposal it would be folly to dogmatise; nevertheless a few tentative conclusions may be offered.

Prontosil is of undoubted value in the treatment of erysipelas. The drug is best administered by mouth. It is necessary for the patient to receive repeated doses in order to maintain the requisite concentration and these are more easily administered by mouth than by repeated injections.

The dosage in our series appears to be adequate. It may be expected to produce a favourable result in about 48 hours—i.e. when about 60 grains have been ingested. No obviously untoward results followed from this dosage or mode of therapy. The drug ought to be persisted in for about a week. (Tonndorf suggests ten days.)

It has little or no effect on local septic lesions which may have been the starting point of the attack.

Finally, we would draw attention again to the quite remarkable results in the age group 50-65 and over, and to the fact that no spread or relapse occurred in any patient while actually taking prontosil by mouth.

We are greatly indebted to Dr D H R Harries, medical superintendent of the North Eastern Hospital, for his

permission to published details of these cases and for his help and advice in presenting them

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF UROLOGY

At a meeting of this section on May 27th, with Mr BERNARD WARD, the president, in the chair, a paper on

Genito-urinary Tuberculosis

was read by Mr JAMES CARVER. It was based on 46 cases under his care in the last four years, most of which had been sent from sanatoriums, where they were having treatment for tuberculosis of urinary tract, lungs, or joints. In 28 cases the lesions were renal and in 10 they were genital. Renal tuberculosis was commonest during the second, third, and fourth decades, 1225 of 1571 cases in a recent series were between twenty one and fifty years of age. Genital tuberculosis occurred at the period of maximum sexual activity. Half the cases in which the disease was in the seminal tract had bilateral epididymitis, the second epididymis becoming involved within a year of the first, in three the testis was so diseased that castration was necessary, while in one bilateral castration had to be performed.

In tuberculosis of the kidney, said Mr Carver, the earliest symptom was frequency of micturition, the next most common was burning and scalding and hæmaturia. No one would wait nowadays for night sweats and hoarseness before sending sputum for examination, but in non sanatorium cases a surprisingly long period often elapsed before genito-urinary tuberculosis was suspected. There was need for wider recognition of the earlier symptoms, and all patients whose bladder symptoms did not improve within a reasonable time should have a complete bacteriological and urological examination. It was unwise to rely on smears alone for diagnosis, on the other hand guinea pig inoculation and cultures had proved reliable in 24 out of 26 cases of renal tuberculosis. Occasionally negative laboratory reports might lead to a wrong diagnosis—e.g., when renal occlusion was present. Briaschi, of the Mayo Clinic, reported that of 621 cases of tuberculous kidney 69 had renal occlusion. Uroselectan was valuable as a diagnostic aid, but its use should be preceded by ordinary radiography of the renal tract to find any calcareous deposits. Often excretion urography indicated which side was diseased. For cystoscopy the speaker always employed a low spinal anaesthetic. Where there was much contraction, and where it was difficult to obtain a clear medium in operating cystoscope should be used. Operation for tuberculosis of the kidney was rarely required very urgently, and everything possible should be done to raise the patient's resistance and general health beforehand, even by sanatorium treatment when this could be arranged. Patient and staff should be on the best of terms for a considerable period before operation. As an anaesthetic cyclopropane was now largely used in place of gas and oxygen, it had the

advantage that no chest complication followed its administration, and also that breathing was very quiet during the operation, and there was sufficient relaxation. The only drawback to cyclopropane in his experience was a tendency to nausea and vomiting in the 24 hours after it was given.

In his Bradshaw lecture Hugh Lett spoke of the advantages of removing the ureter when the kidney had to be removed for tuberculosis, and the speaker's choice was the same procedure. After the vascular pedicle had been divided, the kidney was pushed down towards the pelvic brim, and the wound was sewn up and drained. Then the patient was put into the Trendelenburg posture, and a subumbilical midline incision made. The kidney was delivered to the assistant, who held it vertically upwards while the ureter was being stripped down to the bladder. The ureter was clamped flush with the bladder and divided. The cut end was sealed with pure carbolic and embedded. The pelvic wound was also drained. Several writers had emphasised the importance of removing the perinephric fat, so as to avoid contamination of the operation field and subsequent breaking down of the wound. But Mr Carver thought the perinephric fat played little part in this catastrophe, in his view the causes of it were rupture of the kidney owing to rough handling, and contamination of the wound by the ureteric stump when the kidney had alone been removed. All his loin wounds healed by first intention. Urologists who did not practise nephro-ureterectomy declared that the ureteric stump was able to look after itself. But it was impossible to judge of the condition of the lower third of the ureter from a loin incision. The portions of the ureter which were most seriously involved were the upper and lower thirds.

A condition that was almost as trying to the surgeon as to the patient was tuberculous cystitis in association with bilateral renal tuberculosis, or other condition rendering operation on the kidney impossible. Diathermy had proved very successful in one case in which ulceration and hypertrophy of mucous membrane was present. Mr Carver had had no experience of such methods as injections of 6 per cent carbolic, as recommended by Rovsing, or of chloride of mercury as suggested and used by Guyon, nor of Holland's method of giving potassium iodide internally, and calomel emulsion in oil into the bladder. In carrying out epididymectomy, every effort should be made to preserve the testicle, especially in young men, small abscesses in it should be curetted in preference to castration. When, however, the testicle was severely involved, castration was necessary. In the presence of sinuses there was great danger of wound contamination and A B Cecil's extrusion operation was worth employing. The sinuses were treated with pure carbolic and a circular incision was made around them, then the incision was deepened and the tunica opened. Barney advised removal of the tunica also if it was diseased. Bumpus and Thompson reported 68 cases of genito

urinary tuberculosis in only one of which seminal vesicle disease was present. In 10 the opposite epididymis was also infected, but the seminal vesicle on that side was clear. Of a large series of fatal cases 44 per cent. were found to have died of tuberculosis of the other kidney, 35.5 per cent. of tuberculosis of the lungs and 13.3 per cent. from primary tuberculosis. In other words, 93 per cent. of the deaths were due to tuberculosis. Mr Carver considered that the poor results were largely due to an insufficient building up of the patient's resistance after operation. Patients were very reluctant to submit to prolonged sanatorium treatment especially if they had already had sanatorium régime. They disliked being away from family life, and they feared with good reason loss of employment. Lett had stated that 80 per cent. of the well-to-do recovered completely whereas in those less fortunately circumstanced workers and others the proportion sank to 55-60 per cent., which showed how large a part was played by physical vigour and resistance. Finally genito-urinary tuberculosis should not be regarded as a localised disorder but rather as a manifestation of a generalised disease. Hence the prognosis should be guarded.

DISCUSSION

Mr F E FELDEN said many denied that a renal tuberculous focus ever healed and that might be true. Nevertheless eight years ago he had a patient aged 22, with a definitely diseased left kidney and a grossly diseased right kidney who was passing urine 32 times per night. A right nephrectomy was done and when he saw her six months ago she was very fit—her weight having increased by 3 st.—and apparently comfortable never rising at night. All he had hoped in operating was to give some relief. In removing a tuberculous kidney he would insist on real sanatorium treatment for at least six months.

Mr H. P. WINSBURY WHITE said that in the cases of tuberculous epididymitis he had seen he had always found evidence of prostatic infection though he could not always prove it was tuberculous. Often such patients did not show symptoms which directed attention to the urinary tract—i.e. they might have prostatic infection but no great disturbance of micturition. A large proportion of cases of renal tuberculosis had genital infection also and this suggested that there must be an easy pathway by which the infective material could wander casually from one part of the genito-urinary apparatus to another. It was not easy to regard the infection as blood borne.

Mr HUGH LETT thought that in tuberculous epididymitis the infection was usually lymphatic. Often the testicle showed no obvious sign of tuberculous disease. It was very probable that there was a definite infection of the lymphatics of the vas. In his view once there was a closed renal tuberculosis and the other kidney was sound it was unwise to leave the infected kidneys no matter how well the patient might appear. By removing the ureter with the kidney it was possible to prevent the many distressing cases with a persistent sinus in the lumbar region and a breaking-down wound. In taking away the ureter one removed an important focus of infection which was in direct communication with the bladder. In many patients who ultimately died having had one kidney removed there was found to be tuberculous disease of the opposite kidney. It was also known that there were many patients who

died from disease of the opposite kidney which was not necessarily tuberculous disease. It might be a condition of hydronephrosis. Either the ureter was dilated along its whole extent or there was a stricture at its lower end. In the former case the cause was thought to be persistent contraction of an inflamed bladder. In that way the kidney might become the seat of tuberculosis. Even more important was the development of tuberculous disease in the lower end of the ureter on the sound side. He emphasised the importance of sanatorium treatment for these patients before as well as after operation. In recent cases the importance of bed could not be overestimated.

Mr E W RICHES agreed about the advisability of removing the ureter as well as the kidney. On several occasions he had had to remove a ureter by a secondary operation to clear up either a persistent cystitis or a persistent sinus. He thought that if clinical and bacteriological examination and excretion urography were carried out there was seldom need for pyelography. He was a believer in tuberculin. Its use often brought improvement in the condition of the second kidney when the first had been removed by operation. It was valuable to remember this seeing that many patients could not have sanatorium treatment. As to prognosis, he felt that unilateral tuberculous renal disease had a reasonably good prognosis.

Mr H V WELLS said that in prostatic trouble the infection travelled along the lumen of the vas. In a case with prostatic infection the passage of an instrument might be followed in 24 hours by acute epididymitis. In a considerable proportion of cases of tuberculous epididymitis there was no demonstrable renal lesion. A tuberculous bacilluria might be determined by a focus in the kidney which might afterwards heal.

Mr R OGIER WARD thought the general outlook on renal tuberculosis unduly pessimistic. Mr Carver's series largely composed of sanatorium cases was notable for the proportion in which there were other tuberculous lesions in the body. It was his own custom in both hospital and private practice to ask patients whether they had had disease of bones or joints and he was surprised at the small number who had. He did not often perform nephro-ureterectomy. When should it be done? If the patient had a golf hole ureter or if it was grossly diseased the ureter should come out. If a ureteric orifice moved with respiration it meant it was a rigid ureter and that the kidney was stuck to the diaphragm and the surgeon should be prepared to perform nephro-ureterectomy; and similarly if the ureter could be felt per abdomen.

Mr A E ROUTE agreed about the general undesirability of ascending pyelography for the diagnosis of renal tuberculosis. He had never tied the vas on the apparently sound side in cases of unilateral epididymal tuberculosis. His mind always ran on the possibility of a legal action for one could not swear that a particular patient was not one of the 40 per cent. in whom the disease would not have spread to the fellow testicle.

The PRESIDENT said that if there was tubercle in any other part of the body—particularly lungs, bones or joints—he held his hand until, under sanatorium or other treatment the active lesions had become quiescent or cured. Even a kidney with advanced disease was doing a considerable amount of work. If it was removed the whole of that work had to be done by the other kidney and its chance of infection was increased. As kidney operations

were not urgent, there was every opportunity for careful preparation of the patient. Moreover, tuberculosis of the kidney was not necessarily a progressive disease, it would be curious if the kidney were the only organ in the body that did not show resistance to tubercle. Once the calyces were ulcerated and the pelvis was involved, the lesions were progressive, but even cases of this type could in certain circumstances undergo cure. He did not often do pyelography, sometimes it did not teach as much as did careful examination of urine drawn off by ureteric catheter. If such urine showed pus—whether with or without tubercle bacilli—the kidney should be regarded with suspicion. If a ureter was thickened he removed it, almost throughout its length.

Mr CARVER, in reply, agreed that in established renal tuberculosis infection could spread to the epididymis, prostate, and vesicle from the urethra. He believed the infection often travelled by the blood stream, often the primary lesion was in the epididymis. When in doubt about a kidney sinus he used ascending pyelography.

BRITISH PSYCHOLOGICAL SOCIETY

Dr H CRICHTON MILLER took the chair at a meeting of this society held at the Tavistock Clinic on May 25th, when Prof WILLIAM McDougall delivered an address on the relations between

Dissociation and Repression

These relations, he said, constituted one of the fundamental problems in psychology. Both words were widely used and both were doubtless needed, they probably stood for phenomena of two different orders requiring at least two quite distinct theories for their interpretation. This view was, however, not generally accepted. The followers of Janet had as a rule no use for the concept of repression, while most of the followers of Freud, Jung, and Adler admitted no need for the word "dissociation." This continuing division of opinion might, thought Prof McDougall, be properly regarded as a symptom of the sickness of psychology—a dissociative symptom, or a disorder due to conflict and repression. It was in any case a notable instance of lack of integration of the science of human nature. Many of the more eclectically minded psychologists—who were fortunately more numerous in Great Britain than in any other country—used both words as descriptive terms and recognised the need for two corresponding theories.

Study and experience had led Prof McDougall to treat repression as a dynamic factor which in many cases prepared the way for and led to dissociation. Assisted by various friendly but vigorous opponents of his views he had gradually come to realise that he was confounding under the single term "dissociation," at least two factors which ought to be distinguished—dissociation and disintegration. The first step towards a solution of the problem must be to distinguish the various meanings of the word "dissociation" as used by various authors. Here one must bear in mind the distinguishable conditions of mental integrity or unity, expressed by the harmonious functioning of mind in its normal healthy instances. The study of the normal had been too much neglected in psychology.

A psychologist who regarded the structure of the developed mind as the product of the operation of

a single powerful principle, that of association, naturally saw in dissociation the one abiding principle of mental disorder. Some such logical principle seemed to have invaded Janet's doctrine of dissociation. Though few workers nowadays accepted the old associational doctrines, much uncertainty was felt concerning the principles which must replace or accompany association as the organising processes by which the sane mind became a harmoniously working entity. In his "Outline of Psychology," Prof McDougall had described three principles which governed his doctrine of the mind's structure. He had distinguished two great aspects of the mind's organisation. The first of these was the logical structure, corresponding to the logical relations of the cosmos in general. It grew in two ways, mainly by differentiation of germs of mental structure—mental dispositions—achieved by innumerable acts of analytical discrimination, and secondly by acts of synthetic apperception. The other aspect of mental organisation was the historical aspect, the total structure of the mind. This was built up by innumerable acts of association resulting in the formation of associative bonds between those units of structure which grew up by discrimination and apperceptive synthesis.

BREAKDOWN OF THE HISTORICAL STRUCTURE

There were therefore three distinct processes of growth and three corresponding modes of failure of development and perhaps of breakdown of the products of those three processes. The principal mode of failure for Prof McDougall's present purpose was, he said, the breakdown of the historical structure. This was what he understood by dissociation in the strict sense—an undoing or weakening of the links of association. It was illustrated by cases of complete absence of memory for all concrete facts but complete retention of the use of language and the understanding of things, so that the patient could conduct himself like a perfectly normal person, his chief trouble being that he did not know the names of things, which were attached to the things themselves by associative process. There were also cases in which the function of the logical structure of the mind was arrested. These were the cases of extreme regression in which the patient became like an unborn babe, understanding nothing. The mind was regarded, according to this view, as built up of distinguishable units of structure or mental dispositions, cognitive and conative, which underwent differentiation in various conjunctions and became smaller and larger systems, linked to one another by a multitude of associative bonds. It was a fair assumption that the structure of the mind could be validly translated into terms of neurones and cerebral structure, the mental dispositions being regarded as functional groups of neurones or systems of such groups. It was also a fair assumption that the associative links between such systems were represented in the structure of the brain. Further, mental dissociation might be assumed to involve some kind of impairment of these neural cross connexions. A further and much more questionable and speculative assumption was, however, that neural continuity was the ground of the unity of consciousness, or, in other words, that one condition of unity of consciousness was continuity of the field of energy changes going on in the brain at any one moment. In the latter form this assumption was confidently made by the representatives of the Gestalt school of psychology, and was carried to an extreme in the very questionable doctrine of isomorphism.

DYNAMIC RELATIONS OF THE MIND

In writing his *Outline of Abnormal Psychology* Prof. McDougall had he said, found it necessary to recognise a fourth kind of functional relations between various parts of the total structure of the mind—relations of dominance and subordination. These relations made of the total structure not merely a vast complex system of units all so connected that they might reciprocally influence one another but also a unity in a further and a higher sense an hierarchical system. They integrated the whole organisation of the mind and made of it a harmoniously working unity. They could not be translated like the other relations into terms of neural or cerebral structure. They were strictly dynamic relations. It was very difficult to suggest any adequate picture of corresponding relations between neural systems. These dynamic relations were essentially moral relations or at any rate mainly relations which perhaps had no neural equivalents. For this reason Prof. McDougall had felt compelled to describe the mind as made up of monads, in the sense of relatively independent psychic units. He regarded the integration of the human personality as consisting in the main and most importantly of its maintenance as one harmonious whole by this system of dynamic relations of dominance and subordination. The other structure relations he regarded as *adjutant as instrumental aids to or conditions of integration*. This system was even more important in psychotherapy than the other three.

At this point he had begun to connect the theory of dissociation with the theory of repression. To reconcile and combine the first three systems with the fourth was a fundamental problem and the difficulty of doing so was the chief barrier which still divided psychologists into those who thought of a neurotic disorder chiefly in terms of dissociation and those who thought of it chiefly in terms of repression. Both ways of thinking were right and to combine them only required that certain assumptions should be boldly and consistently carried through. A great army spread over a wide front consisted of many units each with its own internal organisation organised in turn within larger units. These units corresponded to the mental systems or dispositions. Connexion between the units of an army was maintained by a multitude of field-telephone wires. These represented the historical associative structure of the mind which linked up all the mental dispositions. So long as the military units maintained their normal internal organisation and the telephone system was in good condition the various parts of the army were in touch with one another and the army was a whole. A general failure of the telephonic system through a weakening of the electrical supply would correspond to the general relative dissociation of cerebral hemispheres which took place in sleep, hypnosis, fatigue and intoxication. Serious impairment of the lines or receiving instruments of one unit would represent local cerebral dissociation cutting out one special function or group of functions.

DISINTEGRATION WITHOUT DISSOCIATION

The more effective functioning of the telephonic system did not, however, make the army a whole in the higher sense. The telephone wires might carry information about the activities of each unit but they might also carry mere gossip or argument. The higher form of unity in a vastly complex system was best and perhaps only attained and maintained by the organisation of an hierarchical system of

dominance and subordination over and above all the telephonic intercommunication. The telephone system might be working perfectly while the whole army was in a state of complete anarchy. Similarly the associative mechanism of the mind might be unimpaired while the mental integrity was broken down through a failure of the dynamic relations of dominance and subordination. There was disharmony without dissociation.

Relations of this sort were fundamental in the social system even in that of animals. Their extreme and true prototype was the relation between the hypnotist and his subject. There was no physical compulsion but a purely moral compulsion or influence which nevertheless was highly effective. Prof. McDougall did not think that the dynamic relation ship was maintained by the mechanisms of association. Two other possibilities suggested themselves. In an army headquarters might control all subordinate systems by a special set of telephone wires or by wireless. Similarly these dynamic relations might be maintained in the mind by means of special associational links or by a telepathic or direct connexion. Critics who found this hypothesis too speculative might be able to entertain that of special nerve paths or fields of energy not confined to the substance of the neurones.

The next question which arose was how the authority of one part of the mind over the others was attained. The status of a warrior king depended only in small measure on his own qualities and much more on tradition, heredity or custom. He symbolised and controlled the energy of the whole system and could bring it to bear in or against any part. The organisation of an army which rested ultimately on the same principles provided a close analogy with the hierarchical organisation of the mind.

Dissociation therefore resulted from failure of the associative mechanism or structure of the mind. Conflict and repression were disorders of the dynamic or moral relations between dominant and subordinate parts of the mind and led not merely to dissociation but to disintegration. It might be better to use the term disharmony to describe the disorder of the dynamic relation and to reserve the term "dissociation" for cases in which both the structural and the dynamic systems of relations were disordered when conflict and repression had led to severe dissociation perhaps amounting to multiple personality. In many of the graver disorders these fundamental forms of breakdown were certainly combined. In an army a single unit might lose touch with the main body through breakdown of its telephonic communication; this was simple dissociation as in simple amnesia, anaesthesia and paralysis. Secondly the unit might refuse to obey orders; this was conflict. Thirdly the opposition of the unit might be overwhelmed and nullified by superior force; this was repression. Fourthly the rebellion might result in breakdown of communications so that the rebels were isolated. In the body a rebellious unit might be isolated physically as well as morally; here repression had led to dissociation with consequent disintegration. The isolated unit might continue to struggle against the superior force as best it could from time to time.

In conclusion Prof. McDougall said that he accepted the concept of general relative dissociation of the brain and of localised cerebral dissociations underlying various functional defects. He distinguished however between disharmony and disintegration the latter of which in many cases involved dissociation as a secondary result of conflict and repression.

REVIEWS AND NOTICES OF BOOKS

The Facial Neuralgias

By WILFRED HARRIS, M.D., F.R.C.P., Consulting Physician to St Mary's Hospital, and Physician to the Hospital for Epilepsy and Paralysis, Maida Vale London Humphrey Milford, Oxford University Press 1937 Pp 105 7s 6d

In this little book Dr Wilfred Harris surveys his vast experience which now extends over nearly 30 years in the treatment of the many varieties of pain in the face. The style of writing, which amounts almost to a collection of aphorisms, will prove to be of the greatest value and delight to those who already know something about the difficulty of interpreting and treating facial neuralgia, the uninitiated may find it necessary to revise their knowledge not only of anatomical landmarks but of nerve distributions before they seek clinical information from this book and even then may fail to appreciate the significance of the brief comments made on the various kinds of pain. The great clinician often makes up his mind by intuition rather than by reasoning, and it may be difficult or even impossible for him to explain exactly how he assesses certain factors, especially the psychological ones, in any given case. This difficulty is greatest when symptoms are all he has to go upon, and the book shows how even the very elect may sometimes be deceived.

However vague may be our conception of their underlying pathology we must recognise Dr Harris's outstanding contribution to the treatment of the facial neuralgias, of which only trigeminal tic is described in detail. He gives many examples of the beneficial effect of alcohol injection for other conditions besides true trigeminal tic, and he also mentions contra indications to its use. It is not possible to teach in writing the master's touch, and though we can find from Dr Harris's directions the point on the face at which the needle should be inserted, it is only by practice that we may hope to know where it ought to go. The book necessarily shows us what can be done rather than how to do it, and it leaves us deeply impressed.

Accidents and Their Prevention

By H. M. VERNON, M.A., M.D., Member of Technical Advisory Board, National Institute of Industrial Psychology London Cambridge University Press 1936 Pp 336 15s

THE earliest studies of the incidence of accidents in industry showed that some persons were more liable than others to have accidents, and to this phenomenon Eric Farmer applied the term "accident proneness." Accident prone people make up about 25 per cent of the population, and this group accounts for about 75 per cent of all accidents. Another 25 per cent of the population are considered to be accident free, whereas the remaining 50 per cent account for about 25 per cent of all accidents. The doctrine of accident-proneness is still contested by a number of practical works managers in charge of large groups of workmen, but from a statistical point of view it is becoming almost an axiom. Dr Vernon's method of approach to the problem of accident prevention is largely a statistical one. His book contains among other things a comprehensive review of the work and reports of the Industrial Health Research Board to which he has himself made valuable contributions. As he says, "everyone

must be acquainted with persons who are clumsy with their hands, and are liable to break almost every article they touch. It is generally assumed that their accident liability is due to sheer carelessness and lightheartedness, and that they could 'easily' avoid it by taking more thought and care." But some persons retain this liability to accidents under all circumstances, it is associated with a greater tendency to stay away from work on account of illness, and is observed more often amongst unskilled than among skilled workers. In industry a reduction in the frequency of accidents has resulted from the removal from dangerous occupations of persons judged to be accident-prone, but it is not always easy to identify them. Psychological tests devised for the purpose have not proved entirely satisfactory, and Dr Vernon does not seem hopeful that they ever will be, but it is encouraging to learn that accident-proneness can be largely overcome by instruction and training.

The practical man is more ready to accept the view that any factor which lowers the general health tends to increase the liability to accidents, though it is difficult to obtain tangible evidence in its support. Fatigue and the taking of alcohol tend definitely to increase accident liability. Good environmental conditions, such as comfortable air temperatures, well lit workrooms, and a reasonable rather than rushed speed of production, all influence the accident rates favourably. The influence of night work on the accident rates is less obvious, but Dr Vernon cannot doubt that night work is less suited than day work to the physiological rhythm of the human organism. He discusses road accidents at some length in the light of analyses of their incidence, and this section of his book is worthy of serious study by those interested in the preservation of their own lives and those of their fellow men. His main conclusion in relation to the prevention of accidents in general is that the most important measure is to educate the people of all ages and classes and to instil in them a safety habit of mind.

The Lung

By WILLIAM S. MILLER, D.Sc., M.D., Emeritus Professor of Anatomy, University of Wisconsin London Baillière, Tindall and Cox 1937 Pp 210 34s

DURING his long and productive career as an anatomist Dr Miller has perhaps done more to elucidate the finer architecture of the lung than any other investigator. His own contributions, embodying work published during five decades, bulk large in this monograph, but they are modestly woven into accounts of other people's work in such a way as to provide a complete and well proportioned story. Probably Dr Miller's greatest single contribution to the subject has been in demonstrating the morphology, topography, and function of the intrapulmonary lymph channels and depôts. This vastly important system of delicate lymphatics is here delineated in amazing detail. The finer divisions of the air passages, the ramifications of bronchial musculature, and the terminations of pulmonary blood vessels and nerves are also effectively represented. The structural obscurities of the lung have not even now been finally cleared up. The author is, indeed, at pains to show the need for further research in several subdivisions of his subject. He has himself set down a few conclusions which may not escape challenge. Most

readers will probably accept his dictum that the 'interalveolar pore' is only an artefact and will regard as conclusive his demonstration of a continuous lining membrane within the alveoli, but they may not agree that this membrane is necessarily epithelial. Some will be disappointed that greater attention has not been given to cytological detail for instance the common mononuclear phagocyte is barely mentioned. Unquestionably however the work as a whole will meet with widespread appreciation. It is a monumental treatise unique in its field.

British Encyclopædia of Medical Practice

Vol. III. By Various Authors. Under the general editorship of Sir HUMPHRY ROLLESTON Bart. GVO KCB M.D. D.Sc. Emeritus Professor of Physic, Cambridge. With the assistance of Prof. F. R. FRASER, M.D. F.R.C.P. Prof. G. GREY TURNER, M.B. F.R.C.S.; Prof. JAMES YOUNG DSO MD F.R.C.S. Sir LEONARD ROGERS KCSI F.R.C.P. F.R.C.S. F.R.S. and F. M. R. WALSH, OBE M.D. D.Sc., F.R.C.P. London: Butterworth and Co. 1937. Pp. 681. 35s.

CONTINUING its exhaustive survey of the entire field of modern medical practice, the third volume of this work opens with an article on cataract by Sir Stewart Duke-Elder and ends with one on diseases of the diaphragm by John D. Comroe. Some of the articles dealing with rare, obscure or tropical diseases will be of interest mainly to the specialist but others provide plenty of material useful to the general practitioner. In the forefront of these is Sir Arthur Hurst's article on constipation wherein he continues to fight the good fight against the widespread habit of taking purgatives. His wise words might well be taken to heart by those inside as well as outside the profession: 'The vast army of hypochondriacs who are never happy unless their stools conform to an ideal which they have invented for themselves can be cured only by making them realise that faeces have no standard size shape consistency or colour; they may then be ready to follow the example of the dog rather than that of the cat and never look behind them.' Two other important articles, one on coma by Sydney Smith and W. Ritchie Russell and one on concussion and compression by L. R. Broster should help in many a situation where differential diagnosis is both vital and difficult. If W. Gordon writes on the less momentous subject of chilblains he summarises the modern methods but offers no royal road to success in the treatment of this tiresome and common minor malady. Discussing the treatment of the common cold A. H. Douthwaite does suggest a new remedy unfortunately not yet available to the many—to fly for half an hour at a height of 8000 ft. In his article on coliform bacillus infections Clifford Morson details the uses and limitations of mandelic acid therapy. Chassard Moiré's article on pelvic cellulitis however must have been written before protosol was introduced in the treatment of cases streptococcal in origin.

An interesting and significant innovation in a work of this kind is the inclusion of a sound and well tabulated article on contraception by C. P. Blacker and Joan Mallowe who point out (1) that lactation offers very poor protection against pregnancy and (2) that pregnancy may occur after the menopause even several months after menstruation has ceased. The only contraceptive methods recommended are those in use at recognised birth-control clinics and

to protect himself against the extravagant claims made for proprietary contraceptives the practitioner is urged to write to the National Birth Control Association for a list of the more efficient productions on the market. Pediatrics is represented by several articles. Kenneth H. Tallerman and Alice Campbell Rose write on child health and welfare and Reginald Miller on colic disease. Writing on child guidance William Moodie in discussing importance to children of a sympathetic environment observes drily that when dealing with cases of child delinquency it is sometimes among the parents rather than among the children that the real patient is to be found. In the sphere of gynaecology M. J. Stewart and Alan Brevin write on chorionepithelioma and hydatidiform mole and James Young collaborates with the general editor in an article on the climacteric and its disorders. Various dermatological conditions common and uncommon receive attention ranging from the homely corn and bunion by W. J. O'Donovan through various types of dermatitis by Arthur Whitfield and P. B. Mumford, to the redundant crawl-crawl by Sydney Thomson. F. M. R. Walsh contributes three articles on cerebellar disease, cerebral plegia and cranial nerve affections and F. W. Watkinson Thomas two on deafness and deaf mutism. There are also two valuable articles on teeth one by Alan Moncrieff on dentition and one by Sir Norman G. Bennett on dental sepsis in relation to systemic disease. The volume which contains in all 68 articles by recognised authorities is well up to the high standard set by its predecessors.

Practical Orthoptics in the Treatment of Squint

By KEITH LYLE, M.A. M.D. F.R.C.S. Assistant Surgeon Royal Westminster Ophthalmic Hospital; Ophthalmic Surgeon Metropolitan Hospital London and STYLIA JACKSON B.R.N. Senior Orthoptist Royal Westminster Ophthalmic Hospital London. H. K. Lewis and Co. 1937. Pp. 212. 12s. 6d.

THE comparatively recent institution of a diploma in orthoptic training for squint (conferred by the Council of British Ophthalmologists on the advice of a specially appointed board of examiners) has created a demand for text books dealing with this subject. The volume under review has been written with a view to meeting this demand and on the whole it fulfils its purpose in that it supplies an elementary introduction to orthoptic training suitable especially for students. The book is easy to read and gives straightforward and comprehensible descriptions of instruments and methods of examination and treatment. If these are somewhat lacking in detail they are no doubt intended to be supplemented by practical work on the part of the student. In spite of their disclaimer in the preface the authors have not altogether succeeded in avoiding the introduction of controversial matter and it seems regrettable from the point of view of the student at any rate that other principles of treatment besides those approved of at the Royal Westminster Ophthalmic Hospital have not at least been mentioned. The allocation of 40 pages—nearly a fifth of the book—to tabulated results is perhaps rather out of keeping with the character of the work nor does the evidence supplied by these tables always seem to bear out the generalisations in the text. The final chapter on ocular torticollis is the most interesting section in so far as ophthalmologists as distinct from students of orthoptic training are concerned.

GENERAL MEDICAL COUNCIL

SUMMER SESSION, MAY 25TH-29TH, 1937

ON Tuesday, May 25th, the Council commenced the hearing of cases in which certain registered dental and medical practitioners were alleged to have committed infamous conduct in a professional respect, or to have been convicted of criminal offences by courts of justice. In accordance with custom, the Council heard these cases in public and deliberated upon their decision in camera, the public were readmitted to hear the decision announced.

Penal Cases reported by the Dental Board

The Case of William Laird, registered as of 40, Gray's hull, Bangor, Co. Down, Dentists Act, 1921

Mr Laird was reported by the Dental Board of the United Kingdom for systematically canvassing for patients in November, 1936. He did not appear in answer to his notice and was not represented. The Council directed the Registrar (Mr Michael Heseltine) to erase his name from the Dental Register.

The Case of James Sharples Hopwood, registered as of 75, Flinton road, Urmston, Lancs, Dentists Act, 1921

Mr Hopwood was reported by the Board for wrongfully obtaining payment from two approved societies of £4 3s., and £4 11s. 8d., by means of untrue and improper certificates in dental letters falsely stating that certain dentures had been supplied and remade. He did not appear and was not represented. Mr Harper, the Board's solicitor, read a statement forwarded by the respondent in mitigation of his offence and pleading severe domestic trouble. The Council directed the erasure of his name.

The Case of Albert Edward Lloyd, registered as of The Bungalow, North Drive, Cleveleys, Blackpool, Dentists Act, 1921

Mr Lloyd had also been found guilty by the Board of obtaining £3 6s. 6d. in 1934 from an approved society by means of untrue and improper certificates for a denture which he had not handed to the member, this case was reported by the Minister of Health. He had moreover been found by the Board to have undertaken in 1936 the repair of an insured person's denture although he was not qualified to do dental benefit work, and to have retained the denture until the member should pay him the sum which the society would have paid him if he had been so qualified. He did not appear and was not represented. The Council ordered his name to be erased.

The Case of John Kennedy Scotland, registered as of 15, Millbrae crescent, Langside, Glasgow, L.D.S.R.F.P.S. Glasg. 1923

The Board reported that Mr Scotland had been convicted on Oct. 20th, 1936, before the Sheriff Court of Linlithgow at Glasgow, of presenting to various chemists on 20 occasions between May 28th and Sept. 29th 1936, fabricated prescriptions and obtaining from them quantities of morphine sulphate which he had not been duly authorised to procure contrary to Regulation 2 of the Dangerous Drugs (Consolidated) Regulations 1928, and had been fined £10 or 60 days imprisonment in default.

Mr Scotland did not appear and was not represented but Mr Harper read a statement which he submitted in extenuation of his offence. The Council ordered the erasure of his name.

The Case of Edwin Spencer Tebbutt, registered as of 30, Finsbury square, London, E.C.2, L.D.S.R.C.S. Eng., 1905

Mr Tebbutt had been convicted three times of drunkenness. He did not appear, but a personal friend applied for permission to be heard on his behalf, and was allowed to address the Council and lay before it his statement in mitigation, pleading prolonged ill health and financial loss. The Council directed the Registrar to erase his name.

RESTORATION TO DENTISTS REGISTER

After deliberation in camera the President announced that the name of Thomas Ross Graham had been restored to the Register.

Charges against Medical Practitioners referred from Previous Sessions

The Case of William Mervyn Crofton, registered as of 22, Park square, London, N.W.1, M.B., B.S. 1904 R.U. Irel., M.D. '1911, N.U. Irel., who had been summoned to appear before the Council in 1935 on charges of advertising based on press interviews and speeches eulogising the Antigen Laboratory with which he was connected. The Council had found some of the facts proved but had postponed judgment until this session.

Dr Crofton appeared, accompanied by Mr G.W. Pritchard, solicitor. The Medical Defence Union, which had complained, was not represented. The Council considered the testimonials produced by respondent and decided not to erase his name.

Dr Crofton then accused the Council of heinous and unprofessional bias and put in a formal written complaint of their conduct of the case.

The Case of William Douglas, registered as of 282, Goldhawk road, Shepherd's Bush, London, W.12, M.B., Ch.B. 1921, U.Edin., who had been summoned on charges of driving a car while under the influence of drink. The Council had found the charges proved in May, 1936, but had postponed judgment for a year. Dr Douglas appeared, and had submitted the required testimonials. The Council decided not to erase his name.

The Case (adjourned from May 26th, 1936) of David Davidson Watson, registered as of c/o Haigh, 21, King street, Wakefield, M.B., Ch.B. 1926, U.St. And., who had been summoned to appear as a result of convictions for driving a car while under the influence of drink. Dr Watson attended, having submitted testimonials. His name was not erased.

The Case (adjourned from Nov. 25th, 1936) of Walter Campbell, registered as of 59, Jeffroy street, Edinburgh, L.R.C.P. Edin., 1927, L.R.C.S. Edin., 1927, L.R.F.P.S. Glasg., 1927, who had also been convicted of motoring offences and of being under the influence of drink. Dr Campbell had not appeared and the Council's solicitor had not been able to trace him. Dr Campbell again did not appear. Mr Harper outlined the steps he had taken to trace him. After deliberation in camera the Council decided to proceed with the case. The charges were as follows—

That you were convicted of the following offences: (1) on Dec. 12th 1931 at the Sheriff Court, Cupar of being in charge of a motor-car whilst under the influence of drink and were fined £5 or thirty days imprisonment. (2) on Dec. 17th 1931, at Dunfermline Police-court of causing a motor-car to stand longer than was necessary for loading or unloading goods or for taking up or setting down passengers, and were fined 25s. or ten

days imprisonment; and of the following misdemeanours: (3) on August 20th 1935 at the Hull City Police-court of driving a motor-car without due care and attention, and were fined £15 and £3 13s 6d costs, or fifty-one days imprisonment; and were disqualified from holding a driving licence for one month; and (4) on Sept 1st 1936, at the Leeds West Riding Court: (a) of driving a motor-car whilst under the influence of drink (date of offence August 16th 1936) and were fined £15 and £5 16s costs or two months imprisonment in default; and were disqualified for holding a driving licence for twelve months; (b) of driving a motor-car in a manner dangerous to the public (date of offence August 16th 1936) and were fined £10 or one month's imprisonment in default.

Mr Harper described the cases in detail and after prolonged deliberation in camera the President announced that the charges had been found proved, but judgment had been postponed for six months subject to the usual proviso Dr Campbell would be well advised to attend next session.

The Case (postponed from Nov 25th 1936) of *Ernest Stanley O'Sullivan* registered as of 12 Dunowen gardens, Cliftonville, Belfast L. L.M. 1928 R.C.P. Irel.; L. L.M. 1928 R.C.S. Irel. who had been summoned to appear before the Council on the following charge—

That you were convicted of the following misdemeanours, viz.: (1) on June 12th 1933 at the Stockton Borough Police-court of being under the influence of drink whilst in charge of a motor-car and were fined £5 and £1 1s doctor's fee (date of offence June 8th 1933) (2) On May 14th 1936 at the City Police-court Newcastle-on-Tyne (a) of driving a motor-car whilst under the influence of drink, and were fined £10 and £9 7s 6d. costs (date of offence May 13th 1936) (b) of driving a motor-car in a manner which was dangerous to the public, and were fined £2 (date of offence May 13th 1936) and (c) of using a motor-car when the brakes were not in good and efficient working order and were fined £1 (date of offence May 13th 1936); to all of which you pleaded guilty

At the meeting of the Council on Nov 25th 1936 the solicitor to the Council had stated that he had been unable to establish communication with Dr O'Sullivan or to serve the notice of inquiry upon him. The solicitor had accordingly applied for the adjournment.

Dr O'Sullivan now attended accompanied by Mr Oswald Hempton solicitor on behalf of the Medical Defence Union Mr Winterbottom solicitor to the Council put in reports of the convictions and gave details. Mr Hempton addressed the Council giving it Dr O'Sullivan's assurance that he now was and would remain a total abstemious Respondent had he said, been extremely worried and unfit at the time of the convictions. He put in a number of testimonials. Judgment was postponed for a year.

New Penal Cases

The Case of David William Jones registered as of 10 Belaxe lane, London N.W.2 M.R.C.S. Eng. 1914 L.R.C.P. Lond 1914 who had been summoned to appear before the Council on the following charge:—

That you were on Oct 23rd 1936, convicted at the City of Birmingham Police-court of the following misdemeanour—viz. of obtaining credit to the amount of £90 & 6d from the London Midland & Scottish Railway Company by fraud and were sentenced to four months imprisonment in the second division and that your appeal on Dec 1st 1936 against the conviction to the Birmingham Quarter Sessions was dismissed.

Mr Harper explained that the offence had consisted of allowing a lady with whom respondent was living

to issue a "dud" cheque in payment of a hotel bill; the lady had been sentenced to a month's imprisonment at the same time and had said in cross-examination that respondent had had nothing to do with the cheque. Both she and respondent had persistently stated that she had assets.

Dr Jones asked if the lady's evidence might be heard in camera. Mr Harper suggested calling her Mrs Jones. Dr Jones said he could not call her unless she were heard in camera. The Council then went into camera after which the President announced that the Council would postpone judgment until May 1938 subject to the usual testimonials.

ALLEGED CARELESS CERTIFICATION

The Case of Joseph Shibko registered as of 5 Prince of Wales-road, Swansea L.M.S.S.A. Lond. 1926 who had been summoned to appear before the Council on the following charge—

That being a registered medical practitioner you on each of the following dates namely Jan 24th April 11th May 6th and Dec. 17th 1936 signed and issued a certificate of incapacity for work for a person described as William Ward whereas you had not seen or examined the said William Ward on any of such dates or at all which certificates were untrue misleading and improper. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

There was no complainant in this case.

Dr Shibko attended accompanied by Mr W. A. Macfarlane counsel instructed by Messrs. Le Brunswear and Oakley solicitors on behalf of the London and Counties Medical Protection Society.

Mr Harper solicitor to the Council said that respondent had never seen Mr Ward, who was in perfect health and at work all the time his wife was sending in certificates of incapacity supplied by respondent. Respondent, when asked for explanations had replied by his solicitor stating emphatically that the certificates had been given by the doctor to Mr Ward or to someone representing himself to be Mr Ward, and the doctor had never at any time given a certificate without seeing the patient.

Mrs W. M. Ward testified to her statutory declaration stating that she had asked at the surgery for a certificate showing that her husband was unable to work and had been given it without comment or fee. The certificates were produced. She had not mentioned any disease and had not been asked. Her husband had never been to the surgery with her and Dr Shibko had never been to their house. She had also received National Health certificates but had destroyed them. In cross examination she agreed that her husband was not a patient of Dr Shibko. She had seen the book he took the slips from but had seen no counterfoils. The five insurance certificates were at quite different times from the others. The doctor had not asked for any particulars of her husband's number or anything. The certificates had been used to obtain relief in June 1935. Her husband had never had a day's illness. She had been convicted of receiving £33 odd in relief and had been to prison for it. She had not offered or been asked for any suggestion at any time as to what was the matter with her husband. She had simply said she wanted a certificate for him and Dr Shibko had written it without a word more. Shown a blank certificate form she said she had never seen such a form before. She did not know that the other form which she recognised was the form for giving to an employer. She knew that respondent was the poor law doctor for the district. She had told a good many lies in her time but this was the

truth She had never noticed if there was any number on the certificates On the one occasion when the relieving officer had called at the house, she had told him he could not see her husband because the parson was in, this had been untrue She had not had certificates for her daughter The relieving officer had read the certificates She had never sent anyone else to the surgery, nobody but herself knew anything about it She had never paid anything

In reply to the legal assessor, she said she had pleaded guilty at the court

Sir Kaye Le Fleming asked what the National Health certificates were wanted for, witness said nobody had asked for them, but she had shown them to the relieving officer until he had ceased to be satisfied with them

Mr W Ward testified that he had not for nine years lost a day's employment through sickness or been attended by any doctor He had never seen respondent until they met in the police court He knew nothing about any certificates After the police proceedings respondent had come up to witness at the bus stop and twice said he thought he had seen witness in his surgery, witness had twice said "You're a liar"

Cross-examined, he said he himself had obtained poor relief in 1935 and had himself been to the relieving officer for it He knew his wife was on Dr Shibko's list for the Public Medical Service, but did not know how many weeks she had actually paid

Dr Shibko testified that he was public assistance medical officer for Swansea No 3 district, and had been interested in local government work before going there He had a panel practice of some 1800 patients and participated in the public medical service for non insurable persons with an income below £250, having some 300 families on his list In addition, he had a substantial private practice The relieving officer could aid destitution without reference to the medical officer, but when sickness was involved a special form was used (This was the form Mrs Ward had never seen) He invariably used that form, there should be a query by the relieving officer if any other form were used The other form (that on which the certificates had been given) was used only for private purposes—e.g., for a friendly society, or for an employer—and he always used the right form for the right thing He admitted that the certificates in question had been signed by him, but he had never given one to Mrs Ward or signed one without examining a man He did not know Mr Ward personally, 800 people might pass through his surgery in a week and it was impossible to call for evidence of identity He believed he had seen Mr Ward and spoken to him in December, discussing why he should visit a surgery three and a half miles from his home He was firmly convinced that it was William Ward and if not, it must have been someone strikingly like him He was certain that he had made it an invariable and inviolable rule never to give a certificate without seeing the patient He well knew the consequences of giving false or misleading certificates When he gave N H I certificates he used a book with numbered counterfoils, and he always filled in the counterfoils, employing a clerk to make records from them He had thought he had a fraud-proof system, but since the police-court proceedings had taken steps to tighten it up still further He could recall nothing about the first three certificates, but had some recollection of the fourth His written records of

Jan 4th, 1936, showed that he had not seen Mrs Ward's elder daughter then, for he had only issued an infant's cough mixture The adult daughter had first been seen on April 17th, 1936, for a rash on the shoulder, she had complained of nervous trouble in September, 1936 He also produced records of attendance by Mrs Ward with her children of school age It was not his custom to charge for certificates of inability to work if no treatment was given

Cross examined, he said he knew Mrs and Miss Ward by sight well and had thought he knew Mr Ward also He took no steps to confirm the identity of his patients He was certain that Mrs Ward had never come to the surgery with her husband.

Witness answered questions by Dr J W Bone, saying that his recollection of his interview with Mr Ward in December was that he came as a panel patient He had no record of treatment for the brachial neuritis and bronchitis which had then—according to the certificate—rendered him unfit for work. If the patient asked for a certificate for an employer, it was now his custom, but had not then been, to ask for the panel card or look for the record card, and he might not give any treatment In reply to Mr H L Eason, he said he kept no records of patients to whom he gave such certificates, there was no evidence whatever that he had ever seen this man

In reply to the legal assessor, he said he had taken no steps to ensure that the patient really was on his panel. Anyone could walk into his surgery and get a certificate, if they said they were on his panel he believed them The certificates in question had been made out by him during surgery hours

In reply to Sir Robert Bolam, he said he had been in panel practice since 1926

Mr Macfarlane read testimonials to character and called the Swansea relieving officer, Mr Leonard Williams, who stated that he had been there since October, 1935 At that time, and ever since, Dr Shibko had been poor law medical officer A N H I certificate was not accepted by him, except pending the production of the proper poor law certificate The four certificates relating to Mr Ward had been handed to him and he had in fact paid out relief on them Since the police court proceedings he always demanded the proper certificate He had a high opinion of Dr Shibko's carefulness

In reply to Mr Harper, he said he would pay two or three hundred people in two hours and he could not give any detailed recollection of other intermediate certificates

In reply to the legal assessor and members of the Council, he said similar certificates from other doctors had been accepted and paid on without inquiry He had demanded no other certificate between May and December The average practice was for applications for relief to be made by the wife The case had been visited on May 13th although relief had been paid ever since January on a certificate of Dr Shibko's His assistant might have paid other, unrecorded, visits, he himself had never called on the Wards Certificates were not required weekly but only intermittently, as required Personation would be quite possible and no steps were taken to establish identity He would accept the word of a wife that the husband was not fit to make application, Mrs Ward had made such a statement to him

Mr Macfarlane and Mr Harper briefly addressed the Council, and the President announced that the facts had not been found proved to the satisfaction of the Council

ADULTERY WITHOUT ERASURE

The Case of Bardwell Edden Tenson Mosse registered as of 13 King-street King's Lynn M.R.C.S Eng., 1926 L.R.C.P. Lond. 1926 who had been summoned to appear before the Council on the following charge —

That being a registered medical practitioner (1) you committed adultery with Ethel Gregory Johnson a married woman, of which adultery you were found guilty by the decrees of the Probate Divorce and Admiralty Division (Divorce) of the High Court of Justice dated Nov. 2nd 1930 and made absolute on Dec. 21st 1930 in the cases of *Johnson v. Johnson* and *Mosse and Tenson Mosse v. Tenson Mosse* in which you were the co-respondent and respondent respectively. (2) you stood in professional relationship with the said Ethel Gregory Johnson and/or her husband Philip Henry Hildon Johnson. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

Dr Mosse was accompanied by Mr Macfarlane instructed by Messrs. Le Brasseur and Oakley on behalf of the London and Counties Medical Protection Society. Mr Winterbottom read extracts from the divorce proceedings, in which it had been stated that Mrs Johnson was a patient of Dr Mosse. Professional attendance was admitted. In 1929 there had been six attendances on Mrs. Johnson in November and December and there had been uninterrupted attendance on both Mr and Mrs Johnson from then until June 1935 ending with 26 calls on Mr Johnson in January 1935 and on Mrs Johnson two in January two in February four in March three in April and one in June. Three later alleged attendances were not admitted by respondent.

Mr J. A. Parsons solicitor to the respondents previous partnership testified that a monthly book of visits was in the handwriting of Dr Mosse and found in it entries of visits to Mr Johnson on August 1st 1935 and Sept. 4th 1935. He also identified a daily record ledger and an entry in it on August 29th 1935 of attendance on Mr Johnson.

Cross-examined he said the partnership had been dissolved by transfer from Dr Mosse to an incoming partner on Sept. 23rd 1935.

Dr Mosse testified that there had been no adultery whatever before February 1936.

Adultery before that date had never been alleged against him. Since leaving King's Lynn in September 1935 he had not practised medicine but had been selling cars. He had written to the registrar because he was hoping to start practice again and had a partnership in view. He did not wish to enter partnership until an inquiry had been held and the matter settled. He had taken the initiative in the inquiry. He had first met the Johnsons socially when doing a locum for his brother in Norfolk; they had not been patients of his brother. Later he had joined a partnership in King's Lynn and the Johnsons were patients of the partnership and he had attended them. The former Mrs Johnson was now his wife. He had first married in 1929 and the marriage had not proved successful. He had never committed any kind of misconduct or familiarity during the period when he was practising. He had first realised his feelings in July 1935 and had forthwith told the lady that he could never attend her or her husband again and that he must see the husband about it. He had immediately put his practice up for sale. Referring to the entries in the daybooks he said he had not attended Mr Johnson on those days but had entered the consultations in the book because it had been the custom to copy entries into the book from a piece of paper. The doctor consulted did not neces-

sarily make the entry. Until a few days ago he had not known of the attention received by Mr Johnson at that time. Mrs Johnson had needed medical attention in September 1935 but he had not attended her in any way.

Mrs. Ethel Gregory Mosse, formerly Mrs Johnson testified that she had been a patient of the partnership and confirmed Dr Mosse's account of the relationship. There had been no adultery before February, 1936.

Mr Macfarlane and Mr Winterbottom addressed the Council and the President announced that the Council had found the alleged facts proved to their satisfaction but had not adjudged Dr Mosse to be guilty of infamous conduct in a professional respect.

CONVICTIONS FOR DRUNKENNESS

The Case of William Dale Lawton registered as of 80 Princess road, Moss Side Manchester L.R.C.P. Edin. 1903 L.R.C.S. Edin. 1903; L.R.F.P.S. Glasg. 1903 who had been summoned to appear before the Council on the following charge —

That you were convicted of the following misdemeanours — viz.: At the Stockport County Petty Sessions: (1) on August 17th 1922, of obstructing the highway by leaving a motor-car thereon without lights, and were fined £1; At the Manchester City Police-court: (2) on June 2nd 1925: (a) of being drunk whilst in charge of a motor-car and were fined £2 (b) of driving a motor-car in a manner dangerous to the public, and were fined £20 and licence suspended for six months (3) on Sept. 5th, 1927 of driving a motor-car in a manner dangerous to the public and were fined £1 and disqualified for holding a driving licence for two years (4) on Oct. 12th, 1930 of being drunk, and were fined 5s; (5) on Dec. 16th 1930, of being drunk, and were fined 10s (6) on Dec. 31st 1930 of being drunk, and were fined 10s or seven days imprisonment.

Dr Lawton was accompanied by Mr Oswald Hempson, solicitor.

Mr Winterbottom asked leave to add before charge (2) a further charge based on a conviction before the Manchester City Police-court on Jan. 20th 1922 for being drunk in charge of a motor-car with a fine of £2. He added details of the convictions. A Warning Notice had been sent in October 1925.

Mr Hempson said that his client was 75 years old and had been in his present practice for 33 years. He could not give an undertaking of total abstinence as that step might be prejudicial to his health, but he was only keeping the practice alive for his son, who was taking his final examinations this summer and for whom he could make no other financial provision. Testimonials were read and the President announced that judgment would be postponed for twelve months subject to the usual proviso.

A CHARGE OF FALSE PRETENCES

The Case of Alfred Edward Vawser registered as of Redcot March Cambs L.M.S. & A. Lond. 1923 who had been summoned to appear before the Council on the following charge —

That you were on April 4th 1936 after pleading guilty convicted at the Uxbridge Petty Sessions of having obtained from Messrs Waddington & Sons by means of false pretences two diamond rings of the value of £52 with intent to defraud and were sentenced to two months imprisonment in the second division and that your appeals on May 18th 1936 and Oct. 30th 1936 to the Middlesex Sessions and to the High Court of Justice respectively were dismissed.

Dr Vawser was accompanied by Mr Oswald Hempson solicitor.

Mr Winterbottom read newspaper accounts of the proceedings. Respondent had taken two rings on approval and had pawned them for £10 each. He had pleaded guilty, expressed sorrow and offered restitution. While in the R A F in Iraq he had had a severe motor crash which had left him with a tendency to muddle headedness.

Mr Hempton pointed out that the appeals had been dismissed on the technical point that respondent had pleaded guilty. Had he been legally advised at the time he would not have made such a plea. From first to last he maintained that all he had pleaded guilty to was pawning rings that were not his property. He had never been charged before, and was liable to muddle headedness, he had failed to appreciate the subtle legal definition of false pretences. Credit had been given him because he was known and was an officer in the R A F, he had done nothing to induce credit. He had given his own name and address, and had been in uniform. He had wanted to give the rings to his wife, who was very ill, after a miscarriage, but he did not want to take the rings home that night and had nowhere to put them. A pawnbroker's offered safe custody and a rough valuation. Thereafter he was ill for four days, and was worried about his wife and about 150 patients in bed with influenza. He had no lack of money, and could at any time have obtained £500 on a reversion. His confidential reports had been first class. He had now had to resign his commission and had been trying to earn a living as a locum tenens, he had secured excellent testimonials.

The Council did not erase his name.

ERASURE FOR ADULTERY

The Case of Douglas Chetham Pim, D S O, registered as of Thornbury, Brecon road, Abergavenny, Mon., M B, B Ch 1915, M D 1920, U Dubl who had been summoned to appear before the Council on the following charge—

That being a registered medical practitioner (1) you committed adultery with Mrs Anne Alma Ferguson on various dates during January, 1935, and on subsequent occasions during the year 1935, (2) in August, 1933, the said Mrs Ferguson consulted you about the health of her son, and during the years 1934-1936 you also stood in professional relationship with the said Mrs Ferguson and her son and her maid-servant. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

The complainant was Mrs Anne Alma Ferguson, who was represented by Mr J P Valetta, counsel, instructed by Messrs Grover, Humphreys and Boyes, solicitors.

Dr Pim attended, accompanied by Mr Macfarlane, instructed by Messrs Le Brasseur and Oakley on behalf of the London and Counties Medical Protection Society.

Mr Valetta emphasised the importance of the dates in the case. Intimacy was admitted but professional relationship denied. Complainant said that the first act of adultery had been in January, 1935 and there had been no suggestion of it before. Respondent put it first in July 1933, and claimed to have known Mrs Ferguson in childhood. Complainant denied childhood acquaintance, and said she had taken her boy to the doctor in 1933. He had been extremely kind at a time when eminent specialists had given the gravest prognosis. He had flatly contradicted the diagnosis and had secured further opinions.

Mr Valetta read a letter dated September 1934 giving a report on the boy's X ray appearances to Dr Pim, and discussing a regime for the patient.

Dr Pim, he said, had dissuaded the mother from getting a London specialist's opinion, promising to keep an eye on the boy himself. He had done so admirably, and the mother had felt a very great sense of obligation. Dr Pim had poured into her ears a tale of domestic woe, including statements that his wife was unfaithful and that he was in financial trouble. On Armistice Day, 1934, he had introduced her to his wife for the first time and the ladies had conversed for an hour. Afterwards Dr Pim had spoken of divorce and re marriage, saying his wife had suggested it, and suggested also that Mrs Ferguson should make provision for Mrs Pim. Thereafter he had laid siege to complainant, saying he had finished with his wife. Then had come a period in which there had been no communication. In 1935 they had stayed together in Torquay for a week, complainant thinking Dr Pim and Mrs Pim had parted. Next March she had been served with divorce papers citing her as intervener, this had been a complete surprise. Adultery had been alleged on a number of dates. A few days later the petition was withdrawn. Then Mrs Ferguson had discovered that Dr and Mrs Pim were living together and they had begun bombarding her for money. Scurrilous statements were circulated to the effect that Mrs Ferguson had broken up the Pim household. In February, 1935, she had required a dental extraction and Dr Pim had taken her in his car to a dental surgeon—not her usual attendant—and had given the anæsthetic.

Mrs Ferguson confirmed the story told by her counsel. She had first met respondent on the beach at Greystones in 1933, she had never seen him before in her life and did not know he existed until that morning. He had not made love to her at that time and they had not committed adultery during that summer. On the beach they had discussed the boy's education, respondent had urged her to send the boy to a school where he himself was about to be appointed medical officer. She had visited him there and he had shown her over the school and been very kind, and had suggested holiday arrangements. Later in the year he had told her about a "tremendous row" concerning his wife and his partner and had said he and his wife went their own ways. In June or July, 1934, she had met Dr Pim again, having moved to Cheltenham in the February, and in August, 1934, she had been very worried about her son and had sent the X ray report and bad prognosis to Dr Pim and asked for help. Later she had telephoned to ask the best doctor to go to in Cheltenham. The doctor recommended was on holiday and his locum who attended was just going, so next day Dr Pim had himself called, bringing the X ray and report. The boy was in bed and Dr Pim and another doctor had consulted about him, Dr Pim had taken the X ray to a local radiologist and got a second reading of it. She had had four doctors already and had asked if Dr Pim could not look after the boy, who had burst into tears at the suggestion of yet another examination. Dr Pim had at first refused as he did not practise in that district but had at last consented, and had been present at the consultation with the specialist. He had refused a fee but had taken a water colour as a gift. Her brother had pressed her to take a London opinion and Dr Pim had told her not to. He had given her a tonic for herself some patent medicine and she had taken it. She had asked him about a pain and he had asked about an operation she had had and offered to write to the surgeon. Instead she had returned to Ireland and seen the

surgeon. Dr Pim had asked her to find shooting for him there. They had travelled over on the same boat. Between August and November 1934 Dr Pim had brought in a tonic for the boy but had not attended any other member of the household until the maid got influenza in December. He had performed small operations on her hand and foot. The maid had been on his panel. She had felt very grateful and would have done anything she could for him. After the dental anaesthetic in February 1935 respondent had not attended at her house. He had offered to but she would not have it.

Cross-examined by Mr Macfarlane she said she made the complaint in March 1937 because of the calumny by his brother in August 1935. In January 1936 she had written to Dr Pim saying that she would go to the General Medical Council if that were necessary to get Dr and Mrs Pim to speak the truth. The years' delay was due to her nephew's grave illness. She had not heard in March this year that Dr Pim was doing rather well in practice now and had not told two gentlemen in Cheltenham that she was taking proceedings for revenge. She denied that Dr Pim had recognised her on the beach at Greytoness; she had played on the beach there as a child. She had been for walks on the golf links in the evening with Dr Pim at Greytoness but had not had intercourse with him then. He had not done anything professionally for the son in August 1933. They had discussed the school and bullying. She had asked nothing of him; he had volunteered everything. He had sent no bill and she had not thought of suggesting payment. She had asked why he took so much trouble and he had said he would get a guinea a term for him if the boy went to the school he recommended. He had never examined the boy with any instrument; being on holiday he had no instruments. The boy had suffered from travel sickness on the journey from Ireland and Dr Pim had given him a sedative at the hotel. The boy had not disliked him more than any other doctor. At no time had Dr Pim written and refused to attend the boy. He had written a letter to enable the boy to be removed to the new school—as he was a ward in chancery—it said the boy was not in very good health. She had never tried to see Dr Pim or rung him up asking for meetings. He had not proposed to discontinue the friendship; no such letter had been written. She had telephoned in June 1934 and asked him to come but had never previously rung him up. The consultation about the boy was before she ever consulted him about herself. In March or April she had had a sort of caffeine poisoning and her cousin had rung up a nearby doctor; she had paid the bill. She had had a facial burn about this time and had shown it to Dr Pim professionally; he had said it was all right. She had written to the Irish doctor and asked for the report he had sent to Dr Pim; in his reply (produced) the doctor had written that he had no record of a report sent to Dr Pim and had only seen the boy once and found no clinical signs of disease. Yet she still maintained that this doctor had said the boy might die at any moment. The X-ray had been sent to Dr Pim not to her. She did not know what consultation or professionally meant; she used the terms in her own meaning. She had paid the other doctors but not Dr Pim. She had written also to the doctor who had examined the boy in Cheltenham with Dr Pim and he had replied to her solicitor that on August 30th he had received a message from her and had arranged to meet Dr Pim at the house as Dr Pim had the X-ray. He had asked Dr Pim

to get in touch with the tuberculosis officer. He recollected Dr Pim saying he did not want to take on the case as he lived too far away and did not recall his making an examination. He had never regarded Dr Pim as the doctor in charge and had charged for ordinary visits and not for a consultation. He had only understood that Dr Pim would act for him in getting hold of the tuberculosis officer. She did not agree that she herself or any man friend could have done that. The tuberculosis officer had written to Dr Pim that he had suggested lines of treatment to her; he had not made the suggestions to Dr Pim. Dr Pim had shown her the letter but had not given it to her. On the occasion when she had seen respondent's wife Mrs Pim had said she wanted a divorce and told all her life history. She had never mentioned Greytoness or adultery. Dr Pim had had a number of meals with her and had not paid for them. He had given her £20 but that was his mother's money. His mother was almost living on her. His telephone had been switched through to her house but the £20 was not the agreed share of the expense. She had not told the dentist that she would only have gas if Dr Pim gave it or asked for Dr Pim. It had been an emergency. (The letter from the dentist stated that Dr Pim had rung up saying a friend of his had a very bad tooth. He had advised immediate extraction and gas and she had expressed desire to have Dr Pim.) It was not fair to say he was practically living in the flat at the time. In March 1934 another doctor had attended her in April. Dr Pim had gone to practise in Abergavenny where she had written to him. It was not obvious that he was in a very poor state of health and worried to death about the situation. She had gone to live with him in Abergavenny in May. She had lent him a maid as his wife had left him. Mrs Pim had not left in consequence of her arrival. Dr Pim had not cashed cheques for her. Mrs Pim had begged her to do something to help Dr Pim. She had left Abergavenny some time before Mrs. Pim returned.

Re-examined she said she had made every endeavour to obtain witnesses for a slander action against Dr and Mrs Pim because of the scurrilous remarks being made and had been advised that there was no relief to be obtained that way. Rumours were going round both in her Irish home and in Cheltenham. She had appealed to Dr Pim to stop them in October 1935.

Mr Hugh Richard Ferguson, son of the complainant, testified in support of the story told by his mother. Dr Pim had given him some medicine for travel sickness. After his illness in Ireland Dr Pim had examined his chest with a stethoscope and asked various questions. He was in the room during the tuberculosis officer's examination. He had promised to keep an eye on witness at school and had seen him on Sundays and asked if he was keeping all right. He had given witness some medicine as an alternative to that ordered by the tuberculosis officer.

In answer to the legal assessor he said he had only seen Dr Pim at his mother's flat on Sundays and holidays. Dr Pim had never visited him.

Cross-examined he said he had not liked Dr Pim very much. The first bottle of medicine, he thought, came from the chemist and the second direct from Dr Pim.

Miss Margaret Frances Cadell said she had known Mrs Ferguson since childhood and had been at Greytoness in August 1933. She remembered Mrs Ferguson's visit. She had noticed no signs of intimacy between her and Dr Pim and had heard

no gossip She had not known Dr Pim during childhood

Cross examined, she agreed she had said something to Dr Pim to the effect "You know that person, she used to be Alma Gamble"

In reply to the legal assessor, she said she had never seen them together before

Dr Pim gave evidence denying that of the complainant He said he had been born in Ireland and had usually spent his childhood holidays at Greystones He had seen Mrs Ferguson there in 1933 but had not recognised her until after Mrs Cadell had spoken to him Then he had said "Do you remember me? I'm Douglas Pim" She had replied "Great God, we played hero together as children" During the ten days they had been together there she had wept and said how lonely she was as she was being divorced in Australia He had tried to cheer her and had taken her to a dance, both had had alcohol and on the way home misconduct had occurred He had never seen the boy except when sunbathing on the sands and had passed casual remarks about his physical state and recommended his own school. The boy had gone to that school in January but respondent had not known of it until June After the journey from Ireland he had not seen the boy but had said to the mother "Why don't you send him to bed?" He had never heard of the alleged certificate for the Chancery Division until this afternoon and had never written any such letter In the summer of 1934 he had not been consulted by Mrs Ferguson but she had frequently rung him up and he had refused to see her He had given it her in writing that he did not wish the affair to continue. One day in June she had left a message accusing him of getting her over to England and then letting her down She had complained of loneliness and asked him to tea She was being attended at that time by Dr Basil Taylor She said she had tried to commit suicide because of him, he had repeated what he had said before and walked out of the house At no time in that year did he advise her as her doctor She had written again at the time of the alleged tuberculosis (August, 1934) and he had again refused to have anything to do with her professionally, partly—he had said—because of the distance and partly because of the boy's dislike of him He was not clear whether the X rays had come to him direct or not, he had known the radiologist at college He had never put a stethoscope on the boy in his life and had not been in the room when the other doctor had examined him He had gone to the house out of pity and because Mrs Ferguson had asked him to go and introduce the other doctor, a friend of his He had got in touch with the tuberculosis officer at the other doctor's suggestion because the latter was going on holiday next day He had never seen the resulting X ray or a report of it and had handed the tuberculosis officer's letter to the mother He had himself played no part in treatment Apart from the dental gas he had never acted as a doctor to Mrs Ferguson or her son At the time of the gas he had been having all his meals at her flat, it was about a month after she had been cited in the divorce proceedings She had refused to have gas unless he gave it He had paid £20 the first week in January towards the expenses incurred for him in the flat His wife had joined him at Abergavenny on April 1st and from that time he had had frequent correspondence with complainant He had been under treatment by the medical superintendent of the mental hospital at Abergavenny as he had been so worried about the state of his mind She had lent him a maid, who had

acted as his maid, he had never treated the girl. He had last seen complainant in October, 1935 In January, 1936, he had received a letter from her which he had handed to his wife, who had torn it up and thrown it in the fire

Cross examined, he maintained that complainant had forced herself on him from May, 1933, onwards He had relented in June, and had regretted it ever since She had reproached him hysterically over the telephone until he had said "Shut up I'll come round." The housemaster was his nephew and he saw him frequently, he might have handed the tuberculosis officer's letter to him as a matter of convenience She had offered him a picture, he had refused it, she had said she would break it if he didn't take it The petition had been withdrawn partly because he felt he had done the wrong thing in breaking up his home and partly because friends in Ireland told him the type of woman Mrs Ferguson was

Mrs Pim, wife of the respondent, said in answer to examination that her husband had brought Mrs Ferguson to the house in November, 1934 She had then told Mrs Ferguson the substance of her husband's confession of adultery and that she would take divorce proceedings She had filed a petition but had withdrawn it in March, 1935 She had then become reconciled with her husband and had gone to live with him at Abergavenny Mrs Ferguson had come to Abergavenny on several occasions

On cross examination she said that she had withdrawn her petition because she considered it best for her husband and herself She had known nothing about the existence of love letters She had never asked Mrs Ferguson for money She had even refused Mrs Ferguson's offer to pay for the education of her son She may have told her relations that Mrs Ferguson had broken up her home She denied that she had discontinued proceedings because it was hopeless to expect to squeeze any more money out of Mrs Ferguson

Counsel then addressed the Council. After deliberation in camera the President announced that the Council had found the charges proved to its satisfaction and directed the Registrar to erase from the Register the name of Douglas Chetham Pim

Restoration after Removal at Own Request

On Nov 30th, 1935, the Council acceded to an application by Jean Braun, L.M.S.S.A. Lond., 1915, to have his name removed from the Register. On April 25th, 1937, Dr Braun wrote to the Council asking that his name should be restored to the Register, and forwarding a statutory declaration and a remittance in accordance with the standing orders which relate to applications for restoration after non-penal erasure under the Medical Act, 1858, s. 14. The Executive Committee reported to the Council that the standing orders did not expressly provide for the restoration to the Register of a name which had been removed at the practitioner's own request, though in 1921 the Council had been advised that they had an implied discretion to restore such a name and that it was for the Executive Committee to consider the circumstances and advise the Council. In November, 1921, the Council actually restored such a name on the recommendation of the Committee, and the Committee now recommended that the name of Dr Braun should be restored.

The Committee acceded to this request, but passed at once to consider in camera a report from the Executive Committee which stated that the Committee

had been advised by counsel that the standing orders dealing with the removal of names at the request of the practitioners themselves were ultra vires for the Medical Acts gave the Council no power to make such standing orders. The Committee were satisfied that the Council should recognise that its power to remove names of registered medical practitioners from the Medical Register consists solely of the power of penal erasure given by s. 20 and the power of non penal removal given by s. 14 of the Act of 1858. The Council agreed with the recommendations of the Executive Committee that the standing orders relating to erasure at the practitioner's request be deleted.

CONSIDERATION OF THE CURRICULUM

Prof J B LEATHES introducing the report of the Education Committee said that the committee had now completed a full examination of the Council's regulations for the registration of medical and dental students. It had been instructed to consider the regulations with a view to the removal of discrepancies in practice and to suggest the modifications which would be necessary to bring the policy of the Council into harmony with its resolutions passed in May 1936. The committee now said Prof Leathes advised the Council to rescind the regulations and substitute for them the series of recommendations set out in its report. Hitherto the students' register had been compiled from the forms of request for registration which students filled in at the various schools, and had never been complete. Forms were supplied to the schools but only a portion of the whole, sometimes a small one was returned every year. The method was therefore unsatisfactory. The committee now proposed that deans should send to the Council returns of all persons registered as medical or dental students in order that the Council might be in a position to compile an annual register of the medical and dental students who had commenced their professional studies in each academic year. The Council would be content to rely upon these returns for such information as they might require as to the ages at which students commenced their professional studies, and as to the preliminary examinations in general education and the additional examinations passed by students before admission. It would relinquish the policy by which the authorities of the schools and licensing bodies had been encouraged to make the registration of students by the Council a condition precedent to their admission to the schools.

The committee recommended therefore that the present regulations so far as they related to the method of registration should be rescinded with effect from Sept. 1st 1938. So far as the regulations related to the conditions under which students were registered they should be rescinded from Nov. 1st 1938. These two dates had been chosen on the one hand in order that deans entering students in October 1938 should send in their lists beginning with the academic year 1938-39 and on the other hand that the new conditions of admission relating to age, general education, preliminary examinations and the like which would be affected by the Council's new resolutions governing professional education should not come into operation until those resolutions became effective. The committee suggested Nov. 1st as a suitable date. Originally the Council resolved that the new resolutions should come into operation on Jan. 1st 1938 but in November last they had adopted a recommendation of the committee that the date should be postponed to Oct. 1st 1938. The com-

mittee now recommended postponement for another month in order to give the schools a little more time to come into line with the new changes. It would then be clear that the schools would be at liberty to deal with applications for admission in the first term of the academic year 1938-39 under the 1923 resolutions and that applications for admission in any later term should be dealt with under the resolutions of May 1936. The committee therefore recommended that its recommendations, and the resolutions of the Council adopted in May 1936 should come into operation on Nov. 1st next year.

NEW CONDITIONS OF STUDENT REGISTRATION

The principal changes made in the recommendations to accord with the 1936 resolutions were that before registration as a medical student the applicant must be within three months of attaining eighteen years and must have passed a recognised preliminary examination in general education and an additional examination conducted or recognised by one of the licensing bodies. University matriculation remained the minimum standard of general education. A list of examining bodies whose examinations in general education complied with the recommendations was given in the report. The Council should also recognise as complying with these recommendations such examinations of universities in British India, the British Dominions and Colonies and foreign countries as were accepted by any university of Great Britain, Northern Ireland or the Irish Free State as qualifying for entrance or matriculation.

The subjects and scope of the additional examinations to be required were copied from the Council's 1936 resolutions:—

- (1) For all applicants chemistry (theoretical and practical), the elementary principles of general and physical chemistry and of the chemical combination of elements, including carbon.
- (2) For all applicants, physics (theoretical and practical), the elementary mechanics of solids and fluids, the elements of heat, light, sound, electricity and magnetism.
- (3) For applicants who have received their instruction in chemistry and physics before entering universities, university colleges, or medical schools, one or two subjects of general education other than chemistry, physics, or biology at a standard higher than that of the recognised preliminary examination in general education.

The standard of the additional examination in a subject or subjects of general education should be approximately that required in a subsidiary subject offered for the Higher School Certificate at the examinations specified in the recommendations. This phrase indicated the kind of standard the Council had in mind. The School Certificate in England which could be taken at sixteen or under might under certain conditions exempt from university matriculation but provision was made at the schools for an examination at a higher standard—the Higher School Certificate—for boys in later years. This certificate could be obtained by taking either three full subjects or two full subjects and two others at a somewhat less exacting standard called subsidiary subjects. This latter standard might well have been in the mind of the Council as a standard for the additional examinations.

This change which was perhaps the most difficult of all the new changes had not been proposed without due cause. Since 1923 English schools had been teaching chemistry and physics to boys who intended to take up medicine and a pernicious tendency had developed of allowing boys to pass their test in general education at sixteen and sometimes even

before, and then setting them to study nothing but the principal medical subjects for the rest of their time at school. The present suggestion was an effort to combat that tendency and to draw the attention of masters and parents to the necessity of continuing the general education of students after they had passed the comparatively low standard of the School Certificate. Applicants should be able to offer themselves for examination in biology either before or after they were registered as students.

The committee had met in conference all the deans of the London medical schools except three, and they had unanimously agreed that this method could be worked so far as they were concerned.

THE CASE AGAINST DELAY

SIR HENRY BRACKENBURY said that he was not convinced that the postponement of the operation of the new conditions from Oct 1st to Nov 1st was either necessary or desirable. In May, 1936, the Council had prescribed the new curriculum, both preliminary and clinical, and all members had regarded it as a considerable improvement. It should not, therefore, be postponed longer than was fair and necessary to those who had already embarked upon some portion of their medical education, either at school or at a medical school. The effective date had already been postponed once in order to give the public and secondary schools from which most medical students were recruited two full school years' notice of the alterations that might be necessary for the guidance of their senior boys and girls in the kind of curriculum they should take while at school or immediately afterwards. This notice had been ample. The only effect of postponing the change from Oct 1st to Nov 1st, 1938, would be to enable the authorities of medical schools to train the whole body of medical students who joined in 1938 (for nearly all medical students entered in October) under the old instead of the new curriculum. The recruitment of medical students under the improved conditions would be postponed for a year. The postponement would even embarrass the schools themselves, for they might be conducting two different kinds of curriculum simultaneously, according to whether a student registered in October or November.

Prof R J JOHNSTONE also inquired the reason for the change. His own faculty, he said, had spent a very strenuous winter session preparing for the change, and now would not encounter it for another year. He suggested that the same effect would be produced by a postponement to Jan 1st, 1939, or even Oct 1st, 1939.

Prof LEATHES replied that when the new resolutions came into operation they would, so far as they dealt with clinical years, affect not only students who entered after Nov 1st but all students. Only the conditions of entry after Nov 1st would be affected. The committee had been advised that two years was not enough notice and had thought it advisable to give what amounted practically to an additional year.

SIR H BRACKENBURY asked whether a student who entered in October, 1938, and therefore under the old conditions had not a right to claim registration five years afterwards because he had satisfied the old conditions though not the new.

SIR ROBERT BOLAM suggested that this question must be put to the licensing bodies. Sir Henry was not fully aware of the difficulties that beset the officers of medical schools when a new set of regulations was announced. The faculty at his own school

had been bombarded by headmasters and parents with questions whether the pupils who had been under preparation for two or three years could sit in October, 1938, under the old regulations, or whether they must prepare for the new. To upset the whole of the medical curriculum meant years of work for a licensing body in readjusting its arrangements. The postponement meant that medical schools could but need not insist on pupils coming in under the new recommendations. If they gave sufficient notice in their calendar they could alter the succeeding years of the curriculum. He doubted, however, whether the schools had yet got everything ready for the later years. He hoped that the Council would not embarrass the public and the medical schools by bringing the new conditions into force in October and forcing them to deal with many applications for exemption.

Prof L P GAMGEE said that such difficulties were not felt in all schools. His own school was quite ready to adopt the new regulations on Oct 1st. If the change was postponed for a month it would probably cause trouble in the shape of applications from students who had entered under the old regulations to undergo the whole of the old curriculum. If the extra month were given the Council should recommend that all students who entered during October, 1938, should, for the remainder of their course, go under the new regulations.

Dr D J COFFEY, however, spoke in favour of the extra month. The raising of the age to eighteen had been unexpected and the students who came up from schools after doing chemistry and physics might not have done extra subjects, but would have an opportunity of coming in without them. A student, however, who had passed in chemistry and physics by Nov 1st under the old system was in an ambiguous position. Under the old regulations he would have had at the end of the year to pass an examination in chemistry, physics, and zoology, but under the new regulations he would begin on his anatomy and physiology at once. Had he to pass the old examination at the end of the first year and the new at the end of the second? He would have to be exempted from the heavy first examination in chemistry and physics required under the existing curriculum. Dr Coffey also suggested that printed forms should be supplied to each school.

Prof GAMGEE also opposed the postponement to November, but Sir R BOLAM pointed out that the contract into which the new student entered with his medical school gave the school liberty at any time on due notice to alter the syllabus and examination subjects. No school could be run on any other lines.

Prof J W BIGGER thought that great confusion would be caused and students would go to the schools which gave them the most generous exemptions. If the notice given to the schools was not enough the correct procedure would be to hold back the new conditions until October, 1939. November, 1938, was either too soon or not soon enough.

After further debate a motion by Sir H BRACKENBURY to put the date forward until Oct 1st, 1938, was lost by 20 votes to 6.

REGISTRATION OF DENTAL STUDENTS

The committee advised the Council to require that every dental student (subject to occasional exceptions) should be registered in the same manner and under the same conditions as a medical student, but that applicants for registration might commence their professional studies as pupils of a registered dental practitioner instead of at a recognised dental hospital.

or school Under the regulations at present in force said Prof LEATHES a student who took his dental mechanics in his apprenticeship might deduct half the time from his curriculum In consultation with dental authorities including the dental committees of the Council, the Education Committee had decided to recommend that an applicant who after reaching seventeen, had served two or more years as a bona fide apprentice in dental mechanics with a registered dental practitioner should if the licensing body thought fit be allowed to antedate his registration by not more than six months A year was too much to allow out of a dental curriculum of four years A dental student could not do all that was required of him in three for he had to go to a dental clinic for two years and could not pass his biology anatomy and physiology in one only The change would bring no hardship as applications for exemption on this ground were very rare

Many persons would like to see the recognition of outside dental mechanics done away with, but there were always a certain number of deserving men who had earned their living for several years as dental mechanics done very good work and also educated themselves and passed their preliminary examinations They deserved encouragement and made excellent practitioners The committee had therefore recommended what they considered a fair allowance

Mr BISHOP HARMAN urged that dental mechanics should still be allowed one year's exemption from the dental curriculum if they had served two years as apprentices but although the Council agreed that these students were exceptionally deserving people he could not find a second for his amendment to substitute twelve months for the six months recommended by the committee

PUBLIC HEALTH

Sir GEORGE NEWMAN chairman of the Public Health Committee referred in introducing its report to the new resolutions and rules submitted by the Committee for diplomas and degrees for public health. Formerly the rules had provided that candidates should produce evidence of having devoted so many hours to the study of specified subjects but the new rules laid down that a candidate should produce evidence that he had regularly attended a course lasting not less than a stated number of hours This change would said Sir George be more convenient to the licensing bodies The earlier provision that candidates must make 24 daily attendances of not less than two hours each at a fever hospital had been deleted as too difficult to work Candidates would now be required to show that they had attended for three months on the clinical practice of an approved hospital for infectious diseases Of the twenty licensing bodies who had seen the draft rules three only had criticised them substantially The Royal Army Medical Corps found difficulty in Rule 2, which provided that the curriculum could not be taken in less than a year The Committee had felt that the old rules had to be strengthened to slant out the part-time or somewhat transitory kind of training sometimes contemptuously known as night school education

Dr H L TAYLOR suggested that this rule might be relaxed for R.A.M.C. candidates The rules were adopted without dissent

Indian Medical Diplomas

The Executive Committee reported that in February last they had passed a resolution that holders of diplomas granted by the Punjab University

on or after Feb 25th, 1930 should be entitled to registration in the Colonial List The Committee passed a similar resolution on May 24th recognising the diplomas of the University of Calcutta granted on or after Oct 16th, 1936 Sir NORMAN WALKER (President) chairman of the Committee referred to the work of the recently established Medical Council of India in maintaining the standard of Indian university examinations The three universities already on the list were he said those of Bombay Madras and Patna

The Pharmacopœia

The report of the Pharmacopœia Committee was presented by Prof DAVID CAMPBELL, its chairman He said that 43 276 copies of the British Pharmacopœia 1932 had been sold up to date 1000 of them in the last half year Of the Addendum 1936 the number of copies sold since its publication at the end of last year had been 5557 The British Pharmacopœia Commission had reported to the Committee that its principal concern had been the scope of the next Pharmacopœia It had reviewed the monographs of the present work and had made a survey of drugs which had been recently introduced or which were attaining increased use in therapeutics It had compiled a list of those drugs which through decreased use or doubtful therapeutic value might be regarded as no longer worth inclusion in the Pharmacopœia The lists of proposed omissions and additions had been sent to the appropriate Government Departments and medical bodies to the Governments of India and the Dominions and to various branches of the Colonial Medical Service with requests for criticisms and suggestions Information had been interchanged with the United States Pharmacopœia Committee of Revision, which had sent the Commission a report on its plan for the revision of the U.S. Pharmacopœia by means of annual supplements The Commission proposed to watch the plan with interest.

BRITISH HOSPITALS ASSOCIATION

THE weather collaborated with the Mayor of Torquay (Councillor A Denys Phillips) and his fellow townsmen in providing a welcome to the members of the British Hospitals Conference for their annual conference last week. Miss M G MILNE, matron of Leeds General Infirmary spoke at the first meeting upon the status and rôle of the nursing profession in the hospital system. Contrary to the generally accepted idea she expressed the opinion that salaries paid to nurses in training were adequate and in some cases excessive in an endeavour to tempt an increased number of candidates More freedom might be allowed however to the trained staff and it might soon be necessary to undertake the additional expense of allowing senior sisters to be non resident. On the controversial question of the matron's position in respect to the supply of food Miss Milne was content to leave the control to the lady house-keeper with direct access to the house governor while arranging for close collaboration for which she made a powerful plea among all branches of the staff with the nurses

Hospital publicity was the subject of a paper read in the afternoon by Mr C F A BEDWELL, house governor of King's College Hospital Based upon a resolution passed at the last International Hospital Congress he considered the relationship of hospital publicity to health education propaganda In particular he urged that the voluntary hospitals should be given a proper place in the campaign now being organised for next autumn under the aegis of the Ministry of Health Mr Bedwell directed

attention to the admirable paper by Dr Homer Wickenden, of the United Hospital Fund of New York, for the forthcoming congress in Paris, published in the current issue of *Nosokomion* and discussed the relationship of the press to hospital publicity as well as the contribution of broadcasting and the films

VOLUNTARY HOSPITALS COMMISSION

Lord SANKEY made a great impression upon his audience on the following morning in presenting the report of his commission. He based his argument on the contention that there is a general agreement that the voluntary hospital system cannot go on as it is and that something must be done and that had been the opinion of all the witnesses who came before the commission. There was no proposal whatever in the recommendations of the commission to pool funds, but they had endeavoured to create an organisation by which it might be possible to pool experience. In order to deal with the financial difficulties and to provide a means by which the State could assist with grants in aid the commission proposed the appointment of a committee similar to the University Grants Committee as, said Lord Sankey, "the analogy between the universities and hospitals is almost perfect."

Provost SHEEN, in dealing with some of the details of the report from a medical point of view, strongly urged the substitution of auxiliary hospitals for convalescent homes and the abolition of the "process of canvassing masses of people" on making appointments to the staffs of hospitals.

Sir REGINALD POOLE, another member of the commission, said that he had come to its deliberations with an entirely open mind and was in full agreement with the recommendations. He added a personal expression of his interest by offering to contribute to any fund raised to carry them into operation.

The effect of Lord Sankey's speech upon the audience, in which at the outset there was a somewhat critical atmosphere, was seen in the afternoon when at the annual meeting a resolution was passed, almost without discussion, to appoint a special committee to implement the first three resolutions of the commission—namely, the division of the country into hospital regions, the formation in each region of a voluntary hospitals regional council to correlate hospital work and needs in the region, and the formation of a central council to coördinate the work of the regional councils.

It is announced that the first meeting of the special committee will be on June 9th.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg Comdrs E B Pollard to *Arcthusa*, and G S Rutherford to *Pembroke* for R N Hospl, Gt Yarmouth
Surg Lt F Bush transferred to Emergy List
Surg Lt B O'Neil to *Ramilles*

THE LANCET

LONDON SATURDAY JUNE 5 1937

THE CAPITATION FEE

THE national health insurance system, in the twenty fifth year of its age is again faced with the problem of making an equitable adjustment in the capitation fee paid to the practitioners responsible for the medical care of the 18 million insured persons in Great Britain a number which it is proposed to increase by the addition of approximately 1 million juveniles entering insurable employment between leaving school and reaching the age of 16. As on previous occasions the Insurance Acts Committee of the British Medical Association representing the practitioners and the Government have been unable to reach agreement and the question has with the consent of both parties, been referred for determination to an independent court of inquiry. The present inquiry is simplified in that it is not to consider the question *ab initio*. It starts with the assumption that the capitation fee of 9s awarded by a similar court in 1924, is to be taken as the proper remuneration at that time and the task of the present court is to ascertain what changes if any should be made in the capitation fee to meet the changes that have taken place since 1924 in the conditions under which insurance medical practice is carried on. The court of inquiry began its deliberations on May 26th and the Ministry of Health and the Insurance Acts Committee have exchanged memoranda of evidence and rejoinders all of which are reproduced in the supplement to the *British Medical Journal* of May 29th.

The Committee contends that the changes affecting insurance practice since 1924 justify an increase in the capitation fee from 9s to 12s 6d and bases the contention on three main grounds. First, it is pointed out that recently and especially within the last ten years there has been a reorientation of medical thought and a widening of the basis of medical practice which now seeks not only to remove diseased conditions but to promote positive health. The increased responsibility and skill involved in such preventive work is not fully expressed in the increase in the number of the items of services rendered but it is of definite value to the community and should be taken into account in assessing the remuneration of insurance practitioners. Moreover the advance of medical science has increased the complexity of diagnosis and treatment and therefore the amount of time necessarily spent with individual patients. Secondly the Committee produces evidence of an increase in the average annual number of attendances made to each person on a doctor's list. In 1924 the number was estimated by the Minister

at 3.5 and by the Committee at 3.75. Since 1924 the Committee has arranged for the keeping of special records by practitioners in nearly all insurance committee areas, and has thus obtained particulars of over 3000 practices which it is contended show that the average annual number of attendances per person on a doctor's list in the years 1930-36 was 5.02. Thirdly it is put forward that the ratio of practice expenses to gross receipts which was taken by the 1924 court to be 25 per cent, is now 33 per cent. The Committee accepts the view of the Ministry that the fall in the cost of living would, other things being equal justify a reduction of 5d in the capitation fee and that there has been some decrease in motoring costs—not more however than 4.6 per cent corresponding to a reduction in the capitation fee of 4d—but it is contended that these reductions are far outweighed by the increased costs under other heads and by the increased responsibilities and efforts now required in insurance practice. The Committee emphatically rejects the Ministry's view that the young workers proposed to be brought within the health insurance system will need less medical care than the general body of insured persons.

The most important point at issue between the Ministry and the Committee is the extent of the increase in the work devolving upon insurance practitioners and especially in the average number of services rendered to each person on a doctor's list. According to the records specially kept at the instance of the Committee the number in 1930-36 was as already stated 5.02, but an examination made by the regional medical officers of the insurance medical records kept in 600 practices during 1936 showed that the number in those practices was 3.60 and it was found that while the number of surgery attendances had increased by 10.7 per cent as compared with the results of a similar examination made in 1924 the number of visits had fallen by 3.8 per cent. To estimate the net effect of these changes the visits and attendances were weighted in the ratio of 1½ to 1 respectively, the average fee in private practice for a visit being usually about half as much again as the fee for a surgery attendance. The figures were corrected for the omission of records of persons dying during the period under review in each of the years in question and when the weighting is applied to the figures so corrected the totals become 3.99 in 1924 and 4.12 in 1936 showing a net increase in services rendered of about 3½ per cent.—which would be met by an increase of rather less than 4d in the capitation fee as against the 3s 3d claimed under this head by the Committee. In considering the contention that scientific advances have made insurance practice more exacting the Ministry expresses the view that the improved methods have mainly affected specialist practice and that such methods as have been adopted in general practice for example the injection of varicose veins have tended to reduce the total services required. The Ministry gives statistics drawn from insurance medical records and hospital reports which it is suggested afford

evidence that "insurance practitioners have been relieved of some of the more onerous part of their work by recent developments of health services" As regards motoring costs, the estimate in the Committee's memorandum assumes the use of a 15 h.p. model, which it is stated, "is perhaps typical of the car most commonly employed in general practice," and a running cost based on petrol consumption at the rate of 20 miles per gallon The Ministry's figures are based on a car of 9 to 10 h.p. consuming petrol at the rate of 32 miles per gallon

There is an acute difference of opinion on the question of the work that would devolve upon practitioners by bringing persons under 16 years into insurance on their entering insurable employment The Committee presses the view that though in providing medical care for these young people a practitioner's duties will be to a considerable extent preventive and advisory—that he will be concerned less with incapacity than with positive instruction in health and in the early detection and treatment of disease—they will be none the less onerous For such persons the practitioner's services though different in kind will be more rather than less important than those rendered to other members of the insured population It is urged that the period of "transition from the sheltered years of school life to the early years of wage earning is very commonly a difficult and trying one, when the friendly supervision of the family doctor is of paramount importance," and that therefore the new responsibilities it is proposed to entrust to insurance practitioners will be specially important, not only from the point of view of the individual patients but from that of the community of which they form part The Ministry agrees that the period of young adolescence is important for future health, but holds that it does not follow that persons of the age in question require more treatment than older persons, or "that in practice they will demand or receive more treatment", and from evidence drawn chiefly but perhaps not very appropriately from mortality-rates, incapacitating sickness experience, and insurance medical records, it is submitted that the claims which this new class of insured persons are likely to make on the time and energy of insurance practitioners may reasonably be assessed at about half those made by an equivalent number of older insured persons The Ministry concludes, however, that there should be one uniform capitation fee for all insured persons, including the juveniles, and that the fee should be 8s

The chief impression left by the study of the four able documents now published is that the court of inquiry has still a good deal of ground to explore The discrepancies between the estimates made by the Ministry and the Committee respectively of the services to be rendered by insurance practitioners, and of the costs that will be entailed in rendering the services, are so great that further information seems needed of the data on which the estimates were based, and the methods employed in handling these data In the arguments put forward there appears to be some difference of

outlook and emphasis The Ministry seems to consider the question of remuneration in terms of separate items of service—from a strictly quantitative point of view The Committee, on the other hand, rightly emphasises the importance of considering also the kind and degree of the responsibility assumed This is in harmony with the general principle on which the capitation system of payment is based, for in that system the doctor is paid, not—as in the attendance system—for work done but in proportion to the responsibilities he shoulders The court was instructed to have regard in its inquiry to "other relevant factors" and not the least of these is the attainment of the willing coöperation of insurance practitioners in the greatest of national services

NOVEL METHOD OF ADMINISTERING HORMONES

IN our issue of April 11th last year experiments were recorded showing that the effectiveness of testosterone could be much increased by augmenting the volume of oily medium used for injection or by adding fatty acid to the solution The effect was probably due to retardation of absorption and decrease of wastage of the hormones In an annotation we then drew attention to the parallelism between these experiments and earlier work on increasing the effectiveness of œstrone and œstradiol by subdivision of the total dose or by esterification Soon afterwards the preparation and biological examination of a long series of aliphatic esters of testosterone led to the selection of the propionate as giving the optimum combination of intensity and duration of action,¹ and it was shown that, on castrate rats, a constant total dose of testosterone was more efficient given as propionate once weekly than given as free hormone twice daily.²

More recently further tests have been carried out with the esters of œstrone and œstradiol, both on rats³ and on the feather response of brown Leghorn capons.⁴ By the latter test it can be shown that whereas 1 mg. of free œstradiol in one dose has an effect lasting barely one day, 1 mg. as 3 benzoate has an effect lasting ten days, and 1 mg. as 3 benzoate-17 acetate one lasting fifteen days It seemed likely that this effect of esterification depended on either alteration of the solubility of the compound, resulting in slower absorption from the site of injection, or prolonged liberation of free hormone from slow hydrolysis of the esters Some interesting experiments now reported by DEANESLY and PARKES⁵ have a bearing on these alternatives It was found that with androstenediol and *trans* androstenediol an increase in the volume of oily medium actually decreased the effectiveness These compounds are relatively insoluble, and the more concentrated solutions

¹ Ruzicka L. and Wettstein A. (1936) *Helv. chim. Acta*, 19, 1141. ² Miescher K. Wettstein and Tschopp E. (1936) *Biochem. J.* 30, 1977.

³ Parkes A. S. (1936) *Lancet* 2, 674. ⁴ Miescher K. Schulz C. and Tschopp (1937) *Schweiz. med. Wschr.* 67, 68.

⁵ Parkes (1937) *Biochem. J.* 21, 579.

⁶ Deanesly R. and Parkes (1937) *Chem. and Ind.* 56, 417.

readily crystallise out to form a mush of oil and solid matter. It seemed therefore that the greater effectiveness of the concentrated solutions might be due to slow absorption of the crystal mush. This possibility was investigated by administering testosterone to rats and oestrone to capons by the subcutaneous implantation of a solid crystal or compressed pellet. The results were remarkable. A single implantation of a 2 mg crystal of free oestrone feminised the growing plumage of capons for 2-3 months four times as long as a similar amount of the most effective ester. A single implantation of a 2 mg pellet of free testosterone to castrate rats caused greater development of the accessory glands at the end of ten days than the daily injection of a corresponding amount of the propionate in oil.

In view of the increased response in such experiments where absorption of the free hormone was inevitably slow converse experiments were carried out the esters were administered in such a way that absorption into the circulation was inevitably rapid (intraperitoneal injection) or instantaneous (intravenous injection). Given in this way neither oestradiol benzoate nor testosterone propionate showed any prolongation of action, indicating that hydrolysis is rapid once the compound gets into the circulation. Hence it is concluded that the alteration of hormone effectiveness by esterification depends on a change in the solubility of the compound in body fluids and consequent alteration in the speed of absorption from the injection site. DEANESLY and PARKES also point out that since the method of administration has such a profound influence on the effectiveness of a compound and since the optimal conditions differ for different compounds a valid quantitative comparison of two substances can only be carried out after a thorough study of the conditions necessary for maximum efficiency.

A NEW USE FOR ETHYLENE

ENCEPHALOGRAPHY a valuable method of investigation which is often employed in neurosurgical clinics has the one great drawback of producing intense headache vomiting and malaise in nearly all of those subjected to it. Headache may disable the patient for several days the other disturbances usually subside after a few hours. Any method which would give equivalent radiological results, but without these unpleasant though not dangerous accompaniments would clearly be welcomed. It has been assumed by some surgeons that the air itself has an irritating effect upon the brain and meninges. Others suggest that a more readily absorbable gas would cause less discomfort. Oxygen carbon dioxide nitrous oxide and helium have all been used as substitutes for air but there has been no unanimity of opinion that they are any better and air is still used in most clinics.

Dr HENRY NEWMAN of California has used ethylene for encephalography in thirty cases. In water at 20° C this gas is about seven times as soluble as air. Nitrous oxide—possessing a

solubility nearly forty times that of air—was used in a few cases but the gas was absorbed so quickly that the radiograms were unsatisfactory. The pictures obtained when ethylene was used showed good definition, provided that the exposures were made within fifteen minutes of the insufflation. The gas disappeared much more rapidly from the subarachnoid space than from the ventricles. Dr NEWMAN thinks that the headache experienced during the injection was not less severe than when air was used but that it lasted a much shorter time. Patients were usually quite comfortable within three or four hours and were able to get up the following day. The average stay in hospital following air injection was three days, the use of ethylene reduced the average to 1.85 days. The author does not believe that the anaesthetic property of ethylene has any significance, but that its free solubility and consequent more rapid absorption is the reason for its usefulness in these cases.

The removal of cerebro spinal fluid and its replacement by a gas must profoundly affect the dynamics of the intracranial structures. Indeed, it is surprising that in the absence of a space occupying lesion or abnormally fragile blood vessel the central nervous system can sustain such an insult without apparent damage. The withdrawal of the cerebro-spinal fluid which affords support to the meninges and arteries by reason of its density and pressure and its replacement by a medium of such vastly different density, even under a considerable pressure can hardly take place without gross alteration in the tension of the various intracranial structures. This effect will be most pronounced upon the relatively unprotected vessels coursing over the pia in the subarachnoid space and is probably responsible for the immediate severe headache and shock-like reaction. A pleocytosis of the cerebro-spinal fluid subsequently develops and the pressure may remain unduly low or rise above the normal. Various pieces of apparatus have been devised in order that the displacement of the fluid by gas may be gradual and may lead to a minimum of disturbance of the intracranial structures. It is probable, however that whatever method be adopted there will of necessity be a "basal" degree of headache, which will be noticeably severe if the method involves sudden, violent fluctuations in the intracranial pressure. This immediate reaction will clearly be unaffected by the nature of the gas employed. The prolongation of the disturbance for two or three days is to be related to the meningeal reaction. It is possible that if the gas be rapidly absorbed from the subarachnoid spaces the pia-arachnoid reaction may resolve more quickly. This was certainly the clinical observation in Dr NEWMAN'S cases.

Dr Robert Hutchison has accepted an invitation to serve on the committee to review the use of corporal punishment in the penal system of Great Britain. The constitution of the committee is given in our Parliamentary column.

ANNOTATIONS

PROGRESS IN THE HYGIENE OF INDUSTRY

LAST week the committee stage of the Factories Bill was completed in the House of Commons under the able guidance of Major G. Lloyd George and the Bill was ordered to be reported to the House. It may be well to take stock of the present position and to inquire in what respects the Bill has been amended from the point of view of industrial health during such exhaustive discussion. They may be briefly summarised thus.

The Adolescent—Young persons between 14-16 years are not to work more than 42 or 44 hours a week. That is a welcome move in the right direction. We have ourselves consistently advocated a 40 hour week for young persons of these ages. The public weal demands that adolescent men should be both encouraged and enabled to live a full and healthy life during the second physiological period of rapid growth, and we have recently indicated the support given to this demand from many sources.¹ Welcome also is the withdrawal of the clause permitting boys of 14-16 to be employed in certain trades for 56 hours a week between 6 A.M. and 10 P.M. The Home Secretary is to be given power to forbid overtime for young persons up to 18 where "detriment to health" can be shown and also to reduce overtime for women and young persons if it be proved that that overtime is "unnecessary" in a particular industry. The practical value of these concessions is lessened by the well known difficulty of proving detriment to health or the presence of necessity. Only a strong executive could get good value out of these and other vague clauses in the Bill. The number of weeks in the year during which a woman may work overtime is reduced from 30 to 25, and here again the Secretary of State is empowered, under certain circumstances, further to reduce the hours of work.

General Hygiene and Safety—Washing facilities and accommodation for outdoor clothing are now to be provided in all factories, we must recall how wide is the new definition of a factory to realise the extent of this advance. The safety clauses in the Bill were so well drawn at the outset that little alteration has been required, it is good that all old hoists and lifts must be fitted with automatic locking gates.

It is still, however, too early to measure accurately the extent of the improvements in industrial hygiene which the Bill will ultimately contain. A number of amendments were withdrawn in committee upon the understanding that the Home Secretary would reconsider them and, if possible, reintroduce them during the report stage. Some provision has been made for the re-examination of young persons but it is too early also to be sure whether certain important amendments which appeared to be very desirable on medical grounds and which were not incorporated in the Bill have been irrevocably lost—e.g., the setting up of a standard of available floor space in work rooms in order that overcrowding may be avoided. Standards of air space are laid down, in the estimation of which only 14 feet of the height of any work room may be taken into account. Experience suggests that under certain circumstances the available floor space per person is the more important consideration. In corners of a workroom in which a conveyor belt is working there may be gross overcrowding, which may result in severe epidemics of

influenza or sore throat, while the air space of the room is well above the specified standard.

There remains one vital point in the Bill to which constructive criticism, both medical and lay, ought to be directed—viz., to provide effective means to assist the Secretary of State and the Home Office inspectorate in the discharge of the onerous responsibilities which are laid upon them. The Bill, as it is now drawn and amended, is capable of being made a charter of industrial health. Or it may leave things much as they are. Sound and progressive advance in industrial hygiene will depend more than anything on the creation of a strong, representative, and lively advisory council to the Minister. It may be more important now to make sure that the Minister's powers to make special regulations and orders are neither abused nor allowed to remain unused, than it is to obtain an alteration in specific clauses in the Bill. Many of the orders issued under the authority of the Act of 1901, open as they may be to criticism, have been potent instruments for health in so far as they were the expression of medical needs and of practical possibilities as they existed within the several industries.

THE OLD FARMER AND THE RABBIT

THE practice of dentistry is protected by law far more effectively than is that of general medicine. Under the Dentists Act 1921 no person whose name does not appear on the Dentists' Register may practice dentistry or hold himself out either directly or by implication as practising or as being prepared to practice dentistry, and the penalties for contravention of the Act are severe. Nevertheless it is not easy for the Dental Board to obtain specific evidence of practice by an unregistered person which is likely to secure conviction in a court of law. In his address at the opening of the thirty second session of the Board, Sir Francis Acland mentioned one instance in which the difficulties had been surmounted. A person whose name had been penally erased from the register had opened a business described as a dental repair company and had advertised it repeatedly in the local press. The advertisements included a variety of ingenious phrases designed to convey to the uninitiated that the advertiser was a registered dental practitioner, and as such was entitled to practise. In testimony to the ingenuity of these phrases Sir Francis regarded it as inexpedient to recite them, but the Board obtained a conviction on charges of holding out and of practising, penalties amounting to £81 being inflicted. Five months later when further evidence of practice became available the same person was again convicted and was fined £25 with costs. This was a case in which the Board had been pressed for some time by a professional organisation to take action but had waited patiently for evidence sufficient to justify prosecution. Sir Francis added: 'In this connexion I am reminded of a story of an old farmer in my county who was wont after finishing milking to go up to a field on the farm where, looking over the bank, he could see a large rabbit quietly feeding outside its hole, and after taking careful aim at it to miss it. And on turning away sorrowfully he would console himself by saying 'That ther rabbitt ll come out of that there hole wance tu often'. One may hope that his perseverance was ultimately rewarded, but his practice is not one which I can recommend to the Board for their imitation. It is better in most cases that we should

¹ *Lancet* Feb 20th 1937 p. 431

not shoot unless our armament is so powerful that missing is extremely unlikely. I find too that most rabbits will come within extremely short range if given a little time.

CHEMOTHERAPY OF STREPTOCOCCAL INFECTIONS

THE consequences of the discovery of Prontosil are increasing rapidly in complexity. When it was shown that this drug acts by liberating in the body a substance (p-aminobenzenesulphonamide) now known as sulphanilamide and that sulphanilamide itself could be administered with equally good effect, much that had been obscure became plain and when the authors of this secondary discovery reported¹ they had synthesised over a hundred similar compounds without finding any of equal therapeutic efficiency it seemed as if the first shot had struck the bull's-eye and nothing further remained to be done in this direction. Nevertheless sulphanilamide has at least one rival known under the name of Prosepta sine, a report on which by Dr B. A. Peters and Dr R. V. Havard appeared in our last issue. Their experience with it in the treatment of erysipelas has been favourable, and this is in accordance with many previous reports on prontosil itself to which another is added by Dr G. E. Breen and Dr J. Taylor on p. 1334. Meanwhile Dr G. A. H. Buttle and his colleagues at the Wellcome Laboratories who have previously widened the scope of this inquiry enormously by showing that sulphanilamide has a remarkable effect on a variety of experimental infections other than those produced by *Streptococcus pyogenes* now enter the field with two freshly synthesised compounds, diaminosulphone and dinitrosulphone, the calculated therapeutic value of which is even greater than that of sulphanilamide, this being deduced from a comparison of their bactericidal activity *in vivo* and their toxicity. Study of the details in Dr Buttle's paper (p. 1331) will show that the question of toxicity is by no means simple since this appears to vary distinctly in different animal species. Another important difference is that the action of diaminosulphone at least in the blood of a monkey is strikingly persistent.

There is no knowing where these investigations may lead either in the direction of improving the present treatment of streptococcal infections or of broadening the scope of the treatment to include other bacterial infections altogether. It is now quite clear that sulphanilamide is one of a number of chemically related substances able to destroy certain bacteria in the blood and tissues even when present in very small concentration provided that the numbers of bacteria to be accounted for are also reasonably small. This is beyond dispute but its significance is by no means generally understood. A disgruntled writer to a transatlantic contemporary² regards the American equivalent of prontosil as a manufacturer's stunt and observes: "I do not see how this remedy gained such quick recognition but it goes to show that doctors are just as gullible to exploitation of cures as the laity. In the future I shall consign all ultrascientific literature to the waste basket. This letter is succeeded by one recounting the unsatisfactory results of administering the drug in a case of bacterial endocarditis due to *Streptococcus viridans*—a condition long known not to be susceptible to the treatment. Between the incredulous and the

over-enthusiastic this treatment will have a stormy passage before it finds its true level and is properly understood and applied. At the present time it is being overdone in this country by indiscriminate application regardless of the nature of the infection and by unnecessary prophylactic use in obstetrics. Except as an experiment, or perhaps as a forlorn hope, it should be reserved for infections known to be due to hæmolytic streptococci or meningococci: the dosage should be adequate and the effects carefully observed. Only so can clinical data which at present lag far behind our experimental knowledge, be usefully amplified.

A DETAILED ANALYSIS OF ROAD ACCIDENTS

THOSE chapters devoted to road accidents in the book by Dr H. M. Vernon, reviewed on another page are of especial interest in relation to the recent survey by the Commissioner of Police for the London area.¹ The points analysed include fatalities among different classes of persons, the accidents in relation to various classes of vehicles and the hourly and weekly incidence of accidents. It is shown that fatal road accidents increased by 164 per cent between 1920 and 1930 and those in which motor vehicles were involved by 198 per cent over the same period. The number of motor vehicles licensed increased by 160 per cent. Some evidence is adduced to show that the application of the Road Traffic Act of 1930 is helping to restrain this terrible accident rate and the evidence is overpowering that speed is the predominating cause of these accidents. The conclusion reached by the Commissioner for the Police that pedestrians are at fault in about 80 per cent of cases of motor accidents, the innocent motorist being responsible only for about 7.7 per cent, is difficult to credit. After all the increase in the number of road accidents has kept step with the increase in the number of motor vehicles on the roads and not with an increase in the number of pedestrians. Mr A. P. Herbert is not the only one who thinks it hardly fair to blame the poor pedestrian for not crawling about in the long grass at the side of the road while large numbers of potentially lethal projectiles are being shot up and down the fairway. One might wish as much justification blame the soldiers during the last war for the number of casualties which occurred from flying pieces of metal. An analysis of the number of road traffic accidents shows that pedestrians suffer 63 per cent of the total fatalities which occur in built up areas and 20 per cent.—Dr Vernon says only 20 per cent—in unbuilt areas. Motor cyclists on the other hand were killed more frequently in the unbuilt than the built up areas (28 per cent and 12 per cent respectively of the total fatalities) whereas passengers both pillion and non pillion and the drivers of motor cars and lorries also appear to be killed more often in the unbuilt than the built up areas. A graph (p. 106) shows that the drivers of private cars are rarely killed in road accidents.

Railway accidents are responsible for about 3.6 fatalities a year as compared with 7000 from road traffic. Dr Vernon attributes the difference to the two factors of education and compulsion. Another explanation may be that railway trains are not allowed to share roads with pedestrians. The railways have however adopted many forms of mechanical preventive methods with the object of preventing the potential victim from incurring an accident by his own action and this appears to be the keynote of all rational safety methods of

protecting the general public from accidents. It is, or should be, the ideal aimed at in the prevention of accidents in factories and mines, a matter to which Dr. Vernon devotes close and reasoned attention.

HOMEWORK

EARLY last year, after a parliamentary debate on the harm done by homework to the health of school children,¹ the President of the Board of Education said that the Government were determined to see that whatever was wrong was remedied and that the Board was actually in the middle of "a comprehensive inquiry into the whole question." The results of this inquiry have now been published² and throw light on the merits and demerits of home work as it affects three classes of schools—elementary, secondary, and junior technical. The only weakness of the report lies in the fact that the investigators did not include a medical man, so that the physiological and neurological aspects are not as fully considered as they might have been. From the evidence provided it is clear that the problem of homework is not one problem but many, for it differs in different localities and in different schools. The opinions of teachers and parents are correspondingly heterogeneous, but it is perhaps significant that teachers who are also parents are less convinced than most of their colleagues that homework, as at present understood, is a desirable institution. Parents replying to questionnaires were almost equally divided on whether homework has any adverse effect on health, with a small majority in the negative, but when the homework had been reduced a great majority testified to the benefit of the change. Consciously or unconsciously, the parent is often swayed by social or financial considerations, and the greatest incentive to strenuous homework is undoubtedly the desire of teachers, parents, and the children themselves for success in examinations, indeed in one area parents pay teachers to coach pupils out of school hours, while others ask for extra work to be provided. This practice is at its worst in junior schools in preparation for special place and scholarship examinations, and could be checked if it were known that examinations in school subjects have been replaced by the use of intelligence tests for which coaching is futile. But hope of examination success is not the only factor influencing parental wishes and opinions. In one home it may be much easier to provide for undisturbed evening study than in another, one parent may wish the child to have much free time for activities beneficial to himself or to the household, while another may prefer the child to have "something to occupy his mind" or to "keep him out of mischief." One of the few medical opinions quoted in the report is that of an assistant school medical officer, that "during April and May there is every year a marked rise in the number of cases of nervous and physical disorders brought to his notice"—a rise which he attributes to anxiety over the examinations. The investigators' own conclusion is that no homework should be set to children under 12 years of age. In the secondary and junior technical schools the trouble where it exists, is thought to be due primarily to defects of organisation and arrangement, and for these older pupils some reservations are made, but in general it is thought that preparation—i.e., homework or its

alternatives—should not be done on more than five nights a week and preferably on four only, and that the hours per night should be limited to one for those under 14 and to one and a half for those above that age.

The absence of medical experience is again almost the only fault to find in a book³ which describes inquiries at the City School, Lincoln, and contains a striking chapter on the good effects of substituting preparation at school for the ordinary work done at home. The medical aspect becomes especially obvious when one thinks of the needs of individual children suffering from myopia or some other disability likely to be increased by too strenuous a pursuit of higher education.

SURGERY OF ADHERENT PERICARDIUM

IT is more than thirty years since Delorme first proposed the separation of an adherent pericardium from the heart by open operation, and almost as long since Rehn and also Sauerbruch first successfully excised the pericardium, but it was not until the comprehensive paper of Volhard and Schmieden⁴ that operative indications and methods were clearly defined. Paul White,⁵ in his St. Cyres lecture of 1935, also gave a full clinical account and described, among others, ten cases of resection by E. D. Churchill, of which six were completely cured and one benefited considerably. Mr. Pilcher's excellent result described on p. 1223 should stimulate the more frequent diagnosis of a syndrome which, though admittedly rare, must still claim victims in this country as well as in America and on the Continent. A patient showing chronic congestive heart failure with ascites and swelling of the legs, and with a heart that is radiologically smaller than normal or at the most not grossly enlarged, probably has constrictive pericarditis, if there is also a constant increase of the venous pressure in both upper and lower extremities the diagnosis may be made with confidence. In the early stages the process may be arrested and natural compensation may be effected, but too long a delay before operation may present the surgeon with an insoluble problem, for the pericardium may be so adherent that separation is quite impossible. Johnson⁶ has recently written on the use of kymography—which demonstrates the mode of contraction of the heart—in the early diagnosis of the syndrome, and this method of investigation would have the additional advantage of distinguishing between intrapericardial obstruction of the cava and that due to some process beneath the diaphragm. Cranfield and his associates have reported⁷ an interesting autopsy in which the condition was associated with tuberculosis of the lungs. Although they could find no active tuberculous foci in the pericardial scar it may be mentioned that the onset of a generalised tuberculosis has sometimes spoilt the good immediate results of separation.

The risks of operation must not be minimised, but some of the important dangers can now be avoided as a result of Schmieden's work. When it is remembered that he could show patients leading active lives six years and four years after pericardectomy,

it is hard to justify the denial of surgical relief to a patient otherwise condemned to a distressing period of invalidism and to an early death.

OCCUPATIONAL THERAPY

THE value of occupational therapy in fostering self-confidence and desire for renewed health in patients with nervous as well as mental diseases was emphasised by Dr Wilfred Harris on May 20th at a sherry party at Chester terrace organised by the Ladies Guild of the Hospital for Epilepsy and Paralysis, Maida Vale (in future to be called the St. Marylebone Hospital for Nervous Diseases). Lack of occupation he said, tends to aggravate such conditions as depression or insomnia, and the functions of weak muscles and mental process are still further impaired by disuse. The provision of occupational methods of treatment enables the limbs and the mind to be exercised without the patients realising that they are doing work or being set a task. These methods have been developed and systematised since the war in many large mental hospitals, at some of which more than 90 per cent of the patients are constantly employed in various handicrafts such as weaving mat or rug making, knitting sewing and embroidery, bookbinding, making paper flowers and bags and Cellophane or string belts and wood carving, basketry and raffia work apart from kitchen and laundry work and the outdoor occupation in the gardens and farms. It is found at these hospitals that noisy troublesome and destructive patients become quiet social and productive while much less hypnotic and other sedative drugs are required. Dr Harris said that occupational treatment is also being used at certain general hospitals. An Association of Occupational Therapists is now being formed in England on the lines of those organised in America, Canada and Scotland, schools are being started such as the Dorset House School at Clifton and one which Miss Tarrant who demonstrated the work taught after Dr Harris's address and Miss Rivett have opened in London. The educated women trained at such schools are later employed to supervise the patients at their work, to teach them and the nurses the various handicrafts and to select occupations suitable for types of patient requiring sedative or stimulant work or exercises for certain muscles. Co-operation between the medical staff and the nurses with the occupational therapist is of course essential, and also should be supplied with details of the patients' ailments and their special needs. Games for small classes with the medicine hall and rhythmical physical exercises done to music are of value to patients able to walk about. The St. Marylebone Hospital for Nervous Diseases is, according to Dr Harris, one of the first hospitals in England other than mental hospitals to adopt this form of treatment, and although initial expenses have to be met it is hoped that once started the treatment will more or less pay its way.

SUPPLY OF BLOOD TO THE WOUNDED

BLOOD transfusion services—now a necessity in hospital—reach their greatest importance in war, which as Sokolowski puts it represents a traumatic epidemic. The steps taken by doctors in Spain to cope with such an epidemic are described in a contribution by one of them to an international medical journal published in Prague.¹ Remarkably, somewhat bitterly that for countries that can enter on

war when they wish to do so the adaptation of services is comparatively simple the author points out that the plan now generally favoured is to ascertain the blood group of every soldier and when he is wounded provide him with blood either from the slightly wounded or from groups of voluntary donors who can be brought up to the front line when required. The use of cadaver blood would be very awkward on active service because it has to be collected within six hours of death and dealt with in a way that may present difficulties at the front. In Barcelona, before the civil war, there were a few hospitals with excellent transfusion facilities, while others had none of their own. Faced with a war which was unforeseen without any pre-existing army, and with no regular organisation the doctors found it impossible to test the blood groups of all the combatants though much is done by the goodwill and keenness of surgeons at advanced posts. Instead of looking for donors at or near the front, the medical authorities now send up blood from Barcelona obtained from carefully selected volunteers (mostly young women) whose help is invited by radio. A special correspondent of the *Manchester Guardian* on May 7th described how the blood is collected in sealed glass ampoules, containing up to 300 ccm under a pressure of two atmospheres. The tip of the ampoule enters a rubber tube, and at the other end of this tube (which contains a filter a tap and a glass section so that the flow of blood can be observed) is an injection needle sealed in glass. The blood in the ampoules is gradually cooled to 0°C and they are kept in refrigerators at 1-2°C till required. The temperature is then slowly raised to blood heat the tip of the ampoule is broken inside the tube, and the needle is unsealed and inserted into a vein in the usual way. In Aragon transfusion is seldom done in the front line posts, but usually at the casualty clearing stations and apparently it is also done if need be, on the late motor-car and railway ambulances. The daily supply of blood in ampoules from Barcelona which has been organised by Dr F. Duran is stated as 42 litres. It goes to the front in cans fitted with refrigerators and keeps for a fortnight. On the central and southern fronts according to the *Manchester Guardian* the service is different in that the blood is not supplied under pressure but has to be pumped into a vein in the ordinary way. But here as in Catalonia and Aragon blood is if possible sent up to the military hospitals from donors at the base. Elsewhere it has been necessary to look for suitable donors in towns and villages close to the lines.

BASSINI AND HIS OPERATION

FIFTY years ago Edoardo Bassini revolutionised the treatment of hernia by inventing an operation which reconstructed the anatomical relations of the inguinal canal.¹ The principles of his method were at once accepted and so much a matter of commonplace have they become that it is hard for surgeons to believe that less than fifty years ago operation for hernia was all but a complete failure. This fact is indeed a little astonishing for although reconstruction of the posterior wall of the inguinal canal was not done before Bassini did it, ligature and excision of the sac was a recognised procedure, and in young adults with good abdominal muscles complete removal of the sac should have sufficed to give a proportion of permanent cures. The

¹ A paper on the role of the splanchnic in the development of inguinal surgery by Drs L. V. Zimmerman and H. P. Heller appears in *Surgery, Gynecology and Obstetrics* for May 1937.

¹ *Internationale Artliches Bulletin* May-June 1937 p. 43.

explanation seems to be that operation for hernia was held in disrepute and that the surgical text books were unenthusiastic. There was a definite mortality and an appalling percentage of failures. Bassini was the first surgeon to report a long series of cases with few recurrences. His record of 251 operations for non strangulated hernia was published in the *Archiv für klinische Chirurgie* of 1890, and it was this paper that gained international acceptance for his operation. In this series he had had no operative deaths and his follow up showed only 7 recurrences. The first report of the operation was made before the Italian Surgical Society in Padua in 1887. Bassini's approach to the problem was essentially anatomical. There were three objectives in his operation: high ligation of the sac, reconstruction of the posterior wall of the canal, and restoration of the obliquity of the canal, on which depended the valve like action of the anterior and posterior walls in closing the passage. His original operation differs only in minor details from that commonly practised to day. He dissected the posterior wall layer by layer, and sutured fascia transversalis, transversus abdominis, and internal oblique to the upturned edge of Poupart's ligament starting his row of sutures at the inner side of the wound and working upwards and outwards so as to push the internal ring, as it were, outwards and away from the external ring. The external oblique was then sutured in front of the cord. In the other operation most commonly described in text books (Halsted's operation) all layers are sutured behind the cord, and the original obliquity of the canal is ignored.

As mentioned in our last issue, the University of Padua is celebrating the fiftieth anniversary of Bassini's operation by publishing two volumes of "Writings on the Surgery of Hernia" which will include Bassini's original papers. Bassini was appointed to the chair of surgical pathology at Padua in 1882, and was made professor of clinical surgery in 1888, so that the University of Padua can claim much of the glory. But perhaps other countries have some say in Bassini's success, for he studied abroad in Vienna under Billroth, in Berlin under Langenbeck, and in London under Lister and Spencer Wells, being one of the first surgeons to introduce antiseptic surgery to Italy. British surgeons have been invited to the special meeting of the Italian Surgical Society on next Sunday in Padua at which problems of hernia surgery will be discussed.

VOLUNTARY REMOVAL FROM THE REGISTER

UNDER standing orders adopted in 1887 and amended in 1909 the General Medical Council has allowed registered medical practitioners to have their names removed from the Register at their own request. Last week end it was announced that the Council had been advised that it had no power to make standing orders for this purpose, the orders have therefore been rescinded. To allow a practitioner to apply himself for removal of his name is a concession which is possibly capable of abuse, inasmuch as he may take this step to avert the Council's disciplinary jurisdiction. Though the case is not quite parallel, there was recent litigation in the Court of Appeal over a police official who sent in his resignation which was accepted as from a particular date. After the resignation had taken effect, the town council under which he had served purported to dismiss him on disciplinary grounds. The court held that there was no power to take such action against a man who had already resigned. To return

to proceedings which are more fully comparable, it is worth noting that the Dental Board's regulations provide for non disciplinary removal from the Dentists Register. The Dentists Act of 1921 authorised the Board to make regulations "with respect to proceedings before the Board in connection with the removal from, or restoration to, the Register of any name." The regulations require that the dentist who applies to have his own name removed shall make a statutory declaration that he is not aware of any reason for proceedings which might result in his name being erased without his consent. Although the Dentists Act does not seem specifically to authorise such applications by dentists themselves the Solicitors Act has a definite section permitting solicitors to apply. A similar clause is to be found in the Solicitors (Scotland) Act of 1933. In England, under Section 5 of the Solicitors Act of 1932, an application by a solicitor to procure his name to be removed from the roll is made to, and heard by, the Disciplinary Committee of the Law Society. Rules of procedure, sanctioned by the Act, require him to set out the reasons why he wants his name removed and to support them in an affidavit in which he has to declare that he is aware of no cause for any application that he be struck off the roll or suspended from practice. Unless the committee otherwise directs, letters from two practising solicitors to whom the applicant is personally known must accompany the request. The committee has power too to require him to advertise the fact of his application and the date of the hearing. Provision is made for objections to be raised. These precautions seem sufficient to prevent abuse. It is reasonable to allow a professional man to ask that his name be taken off the professional register for non disciplinary reasons. The fact that in the case of the solicitors Parliament expressly sanctioned such a course of action presumably creates the inference that no such rules may be made where, as in the case of the Medical Acts, Parliament was silent on the point. In spite of the curious suspicion of some of our legislators who believe that every proposal affecting the medical profession is an attempt to bolster up monopoly, there seems no reason why Parliament should not now expressly provide for the registered medical practitioner the facility already conceded to the solicitor.

In the rearrangement of the Cabinet following Mr Neville Chamberlain's appointment as Prime Minister Sir Kingsley Wood retains the Ministry of Health, but Mr R. H. Bernays succeeds Mr R. S. Hudson as its parliamentary secretary.

In a presidential address to the seventh English speaking Conference on Maternity and Child Welfare in London on Tuesday Sir Kingsley Wood announced that it has just been ascertained that last year the number of maternal deaths per 1000 living births in England and Wales was 3.81, compared with 4.11 in 1935. This is the lowest rate since 1922.

The death is announced of Sir Ernest Morris at the age of 71. On his retirement in 1930 he had been house governor at the London Hospital for 27 years. Originally transferred from St Thomas's Hospital as chief pharmacist, he was early associated with the late Lord Knutsford in installing new operating theatres and in training the theatre staff in new methods of asepsis. He was later appointed secretary and then house governor of the hospital and wrote its history. In August 1914, he was lent to the War Office to assist in equipping hospitals at the front. He was made C.B.E. in 1920 and knighted in 1932.

SURGERY 100 YEARS AGO*

By R E KELLY CB MD FRCS

PROFESSOR OF SURGERY IN THE UNIVERSITY OF LIVERPOOL
AND SENIOR SURGEON LIVERPOOL ROYAL INFIRMARY

CENTENARIES are for remembrance and in the centenary year of the Medical Institution I thought it would interest the members if I attempted a picture of surgery a hundred years ago.

Before however I come to the purely surgical aspect of 1837 it will be well to recall the unrecorded background against which the surgeon of the time carried on his work and to remind you of the subjects of his thought, his conversation and his interests.

Starting his career as an apprentice he would have attended one of the two anatomical schools in Liverpool, walked the hospital like Bob Sawyer and passed his qualifying examination as a Licentiate of Apothecaries. Possibly he would have journeyed to Edinburgh or London taken the membership of the Royal College of Surgeons and then if his aim had been to become a surgeon visited Paris to see the work in the Hôtel Dieu. He might easily have had some war experience in the Navy and he would have returned to Liverpool to await an appointment at the Dispensary or the Infirmary. He would have had a large and mixed general practice which would have brought him into intimate contact with all types of patients.

Standing on St James's Mount with a rich ship owner he would have gazed through a forest of masts at the busy scene of the Slovinc crowded with shipping and watched the majestic sweep of the latest arrival at its anchorage. The talk would be of freights cotton the abolition of slavery the Reform Act and the new railway. Then descending the hill to the narrow crooked and noisome slums to attend a fever case in a cellar dwelling he would hear of reduced wages the difficulty of rearing children and the high cost of clothes fuel and light. Illuminating gas had only recently emerged from its primeval chaos to a municipal usefulness, and was used solely for street lighting street lighting

was indeed necessary as even in towns one fifth of the streets were never cleaned, drained or even paved. Plumbing though Harrington had invented it centuries before, was not extensive. Even if our surgeon had lived in one of the Georgian mansions fringing Everton Hill—the elegant district—he would have inhabited a house devoid of a bathroom. Envelopes and cigarettes were among the uninvited necessities of life and in the list of the newer luxuries which had been the ruin of the country Peacock had to fall back on blameless tea late dinners and the French Revolution.

* * *

A good idea of surgery is given by the masterly lectures of the famous Astley Cooper published in the twenties. Inflammation hemorrhage and ulceration occupy a disproportionate amount of space. Bleeding was still popular especially in head injuries. There is a record of one patient who recovered after 130 oz of blood were removed in the space of 11 days. Aneurysms must have been exceedingly common. Astley Cooper probably tied most arteries in the body and on one occasion actually tied the abdominal aorta though without success. He had seen seven separate aneurysms in one man. Although he dealt with hundreds of aneurysms in men he records only 8 cases in women. He was aware of the dangers of secondary hemorrhage when the usual long ligatures came away and on one occasion he actually used a catgut ligature and cut the ends short. It was for a popliteal aneurysm and the artery was the femoral. No suppuration followed. He tried the same method several times subsequently but was never again able to prevent suppuration. What a tremendous observation this was!—and how near to a great discovery! The world had to wait for 40 years before the genius of Lister unravelled these conflicting results.

* * *

Astley Cooper's chapter on hernia shows that the only important operation for its relief was the operation for strangulation. Before any operation was advised the unfortunate patient was given a tobacco enema to relax the parts. He was then strung up inverted on the back of a porter back to back with the calves resting on the porter's shoulders. Cold water was then freely poured over him. If

* From a presidential address to the Liverpool Medical Institution on May 31st on the occasion of its centenary. The full text appears in the *Liverpool Medical-Chirurgical Journal* (1937) 43.

after all this, taxis failed, operation was done and the strangulation reduced. Surgeons had a holy dread of the peritoneum, and the abdominal cavity was never entered without misgivings. Should the bowel have perforated, then the wound was merely opened like an abscess. The few who recovered from this operation were left with a fecal fistula which was later treated with a Dupuytren's enterotome, that ingenious instrument invented a century before Paul's method of enterectomy.

There is an amusing description in this same chapter on hernia of a butcher who had to be medically examined for the militia. He produced in himself a very large artificial scrotal hernia by nicking his skin, applying a blow pipe to the hole, and blowing himself up until the surgical emphysema was large enough to mislead the Army authorities. The method was then in use for flaying animals, and is still used by whalers on the harpooned whale to keep it afloat.

Hydroceles were tapped and sometimes injected. Astley Cooper's favourite injection was port wine. This reminds me of some interesting Lancastrian reminiscences published in 1837. There is an account of a surgeon who, whilst awaiting the effect of a tobacco clyster in a case of strangulated hernia, consumed the best part of a bottle of port. This gave him such courage that, with his first cut, he sliced the integuments down to the gut and perforated the bowel. "Not a word or exclamation was uttered, but everyone expressed by a vermicular movement that the affair was desperate. The surgeon laid down his knife—the gazers vanished, the wound was dressed, the woman put to bed, and, in due time, encased in her coffin."

The great operation for the surgeon 'appears to have been the cutting for bladder stone.' The operation of lateral lithotomy, introduced into England by Cheselden, probably from Frère Jacques' work on the Continent, was really an operation of fine skill. It had to be performed on a squirming man trussed up and supported by two or more strong assistants. The knife had to engage the sound at a proper depth in a bleeding wound. The direction of the cut had to be so exact that neither the bulb, the rectum, nor the pudic artery was cut. The enlargement of the prostate must have been a common additional complication, and perforation of the bladder by the sharp end of the gorget often resulted in the stone finding its way into the abdominal cavity and the whole operation had to be done in seconds or minutes. Bland Sutton once said that the Spanish bull fighter had to aim at a target on the side of the bull's neck no larger than 4 cm in diameter. The extremely rapid operation of lithotomy on a sentient patient must have entailed the same anxieties, and demanded the same skill and accuracy as the coup de grace of the matador.

* * *

The two great Liverpool surgeons of the eighteenth century were Henry Park and Edward Alanson. Park was the first surgeon to suggest excision of the tubercular joint instead of amputation, and Alanson the first to improve the method of amputation. Alanson was well ahead of his time. As early as 1779 when only 32 he published his great work. It is said that he always washed his hands and instruments before an amputation. Many of his cases healed by first intention, and he gave details of 40 consecutive amputations without a death, a most brilliant record for that date. He suggested country hospitals, iron bedsteads, clean bed linen and open

windows. Some years ago Mr R W Murray gave us a delightful account of his life, and in the recent history of Bickerton you may read how modern were Alanson's ideals.

Park, Alanson, and another surgeon called Lyon conceived the idea of a reading club about 1770. They proposed to buy new publications conjointly, and divide the books at the end of each year. Before the plan was instituted the physicians joined them, the books were deposited in a room in the Infirmary, which became the nucleus of the first medical library.

* * *

In 1833 John Rutter, a quaker, the foremost physician of Liverpool at the time, thought that the Medical Society and Library were in need of a better house. He prevailed on the mayor and corporation to give to the doctors in Liverpool a free lease on a piece of land at the corner of Mount Pleasant and Hope street. This land had been a bowling green and was valued at £557. He raised funds for the building, which was to contain rooms for both the library and a lecture theatre for debate. He persuaded the corporation not only to give a lease of the land at a peppercorn rent, but to give a grant of £1000 towards the cost of the building. Rampling was the architect. The building cost £4000. The doctors themselves subscribed over £1000, and the lay public £242.

Precisely on this day, May 31st, one hundred years ago, our building was opened. There was then a debt of £900 on it, but this was wiped off by a bazaar organised by Mrs Dawson, the wife of one of the Infirmary surgeons.

Rutter lived only a year after accomplishing this great work. He was our first president. His ambition was that this should be a place which would promote the union and the interests of doctors, the health and welfare of the community, a place for study and mutual instruction, and a habitation for the library.

All these aims have been accomplished, and should Rutter, looking down from the Elysian fields, be aware of our meeting to day, he will, I think, be as proud of this, his only child, as we are of honouring his illustrious memory.

Liverpool Medical Institution

1837—1937

"What Does, what Knows, what Is, three souls,
one man"

WHAT better terms of reference could a medical society have than the gloss of Theotypas, in Robert Browning's "A Death in the Desert," which develops and expands this doctrine? For medicine is not merely the practical work of tending the sick, nor even the intellectual excitement of studying disease, it is warmed and animated by humanity, in a common human experience and endeavour. In this uneasy modern time of mass movements and the despising of the day of small things, when institutions and abstract ideologies are proclaimed in high places as more important than persons, it is wholesome to recall that medicine stands where it does because of the lives and achievement, through the ages, of a great host of individuals, some brilliant with genius, but most of them ordinary folk—"so little starres as have no name, no knowledge taken of them."

It is just a hundred years ago that the founders of the Liverpool Medical Institution met together for

the first time in the present dignified building which has given a local habitation and a name to the more corporate activities of those who practise the art of medicine in and about Liverpool. They foresaw it as the common centre of every useful and honourable professional undertaking—from the securing to medical men of a fair and just remuneration for their services to the purposes of study and mutual instruction and an authoritative helpfulness in all matters affecting the health of the town. As a necessary foundation for these activities they hoped that it would be a means of uniting the different members of the profession in a firm and compact body disposed at all times to co-operate strenuously and cordially in the prosecution of every measure which may conduce to the interests of all.

The idea of establishing such a common centre grew naturally (and surely inevitably) from a small medical reading club which was the origin of the present medical library housed in the Institution. It grew inevitably for Francis Bacon's words are especially true of medicine. Natural Abilities are like Natural Plants that need Pruning by Study; and Studies themselves do give forth Directions too much at large except they be bounded in by Experience. For the physician scientific facts are but the food which must be metabolised if the mind is to bring forth fruit. A man must always be busy with his thoughts; he must exercise his intellectual powers as earnestly as an athlete trains his muscles if judgment is to mellow. It is given to very few to live alone and yet keep a sense of proportion; most of us need the criticism and help of our fellows and thus we can get in calm, disinterested and sincere discussion. In a live medical society men bring their knowledge and experience into the common pool not to display but to convey information. It is indeed the tradition of our ancient and honourable brotherhood that a man shall gladly and honestly submit for the judgment and approval of his colleagues anything which may help to increase the body of medical knowledge. And when a man reveals to his fellows what he knows, he cannot but reveal also to some extent what he is. More important even than discussion and conference is the fellowship of a medical society with its stimulating contacts of personality with personality. Here especially may be nurtured and realised the conception of medicine as the profession of a kindly courteous, sincere, and cultivated gentleman.

This centenary is therefore the anniversary not only of the foundation of a building but also of a living medical fellowship. Those who will meet within its walls to commemorate the great occasion will surely feel that they are compassed about with a great cloud of witnesses. As they cast their eyes back through the years they will rejoice at all excellence of achievement and they will look

The Orthopaedic Memorial Library. The inscription reads: To Hugh Owen Thomas and Robert Jones the founders of orthopaedic surgery.

forward with solemn resolve to maintain the fine traditions of their forebears.

The Celebrations

The programme began on Sunday afternoon when a service was held at the Cathedral attended by members of the Institution in academic dress and when members of the Guild of St Luke, SS Cosmas and Damian met at the Catholic Cathedral site for benediction. On Monday afternoon at the Institution honorary membership was conferred on the Presidents of the Royal College of Surgeons of England, of the General Medical Council of the British Medical Association, of the British College of Obstetricians and Gynaecologists and of the Manchester Medical Society as well as on Sir James Barr, Mr C Thurstan Holland, and Mr Frank T Paul. The new honorary members were introduced by Prof. John Hay. After that Dr Hugh A Clarke was congratulated on the attainment of his jubilee of membership. Prof. R E Kelly then gave his presidential address. In the evening the centenary dinner was held at the Adelphi Hotel. On Tuesday afternoon the new library of orthopaedic surgery, commemorating Hugh Owen Thomas and Robert Jones was formally opened and Mr W Rowley Bristow, president of the British Orthopaedic Association, gave the Hugh Owen Thomas memorial lecture. The programme ended with an At Home in the town hall given by the Lord Mayor.

MANFIELD HOSPITAL.—This institution is endeavouring to raise £10,000 for a new women's ward. At present extra beds for female cases have been provided by alterations to the balconies of two wards and accommodation is strained to the utmost.

TRANSFERENCE OF A CROFTON HOSPITAL.—St Mary's Hospital Crofton will remain in trust of the Crofton mothers and infants welfare centre and had its administrative work transferred to Crofton corporation and the expenses of the institution will be paid from the general rate fund. In order that the hospital may qualify as a training school under the Central Midwives Board a resident medical officer will be appointed.

PUBLIC HEALTH AND HYGIENE

A JOINT ANNUAL CONGRESS

As recorded in our last issue, the Royal Institute of Public Health and the Institute of Hygiene met in joint congress at Margate on May 25th under the presidency of Lord HORDRE.

Captain G. S. ELLISTON, M.P., president of the section on State medicine and industrial hygiene pointed out that this year, a hundred years after the passing of the Act imposing registration of births and deaths, the Government was to sponsor a campaign to interest the people in the maintenance of health by increased use of the services provided by local authorities and voluntary organisations. He approved of this measure, for in most areas health services were more or less complete and further progress must come from the people themselves, for example, only 50 per cent of pregnant women went to antenatal clinics, many cases of tuberculosis were diagnosed too late, and attendance for later treatment of venereal disease was very lax. Reminding the audience that most services were promoted by the force of public opinion, he passed on to the consideration of some conditions now calling for attention. The first was chronic rheumatism, a condition about which no steps commensurate with its importance had yet been taken. Others were noise, cremation, smoke abatement, mental welfare, and child guidance.

HOUSING THE BIRTH RATE

Dr J. GREENWOOD WILSON (M.O.H. for Cardiff), in a paper on the place of the health department in housing administration, maintained that the health committee should be made the paramount committee for housing administration. The medical officer of health should be encouraged to take more interest in housing both before and after he entered the public health service, and greater use should be made of the health department in branches of administration such as allocation of tenancies, disinfection and estate social work.

Speaking on the problem of the smaller authorities in the rehousing of overcrowded families, Dr N. E. CHADWICK (M.O.H. for Hove) referred to some of the difficulties arising out of the overcrowding provisions of the 1935 Housing Act. In his district, at the time of the survey of overcrowding in January, 1936, 96 houses were found to be statutorily overcrowded, by June this number had been reduced to 69, and more recently it had fallen to 38. On the other hand, it was fully realised that fresh crowding had occurred at other houses. There were three ways in which large families could be housed—by converting two houses into one, by building new houses of sufficient size, and by acquiring existing old large ones. Houses built on sites far distant from the original home of the tenants could hardly be construed as "suitable alternative accommodation."

Dr CARYL THOMAS (M.O.H. for Harrow) spoke on certain aspects of the declining birth rate. He reviewed briefly the general situation, pointed out the effects both of a fall in population and of a changed age composition of the population, and summarised measures taken, more particularly in some of the continental countries, to arrest the decline.

FOOD POISONING MILK

Dr F. R. JONES (pathologist to the Kent county council) speaking on the epidemiology and bacteriology of food poisoning, restricted his definition to

acute gastro enteritis caused by the ingestion of food or drink that contains either living bacteria or toxic substances produced by them. Such a definition excluded botulism. Since Gærtner isolated *Bacillus enteritidis* in 1888, 26 other members of the salmonella group had been discovered. In certain cases of food poisoning however no organisms could be found, and the illness appeared to be due to the formation of a heat-stable toxin in the food. Many of these organisms were ordinarily non pathogenic, but under certain conditions of growth appeared capable of elaborating highly toxic substances. Among the incriminated were *Staphylococcus aureus*, *S. albus* (the commonest) members of the salmonella group, *B. coli*, *Proteus vulgaris*, *P. morganii*, *Streptococcus viridans*, and a micrococcus associated with milk. It was not known whether specific toxins were elaborated by the bacteria or whether the toxin was formed from breakdown products of the dead organisms, but presumably the bacteria multiplied and elaborated their toxin in the food before its consumption, the subsequent cooking destroyed the organisms but did not materially affect the toxin. Seasonal variation in incidence was less conspicuous in this type of food poisoning than in that caused by the more common salmonella type. The morbidity rate was high (75 to 100 per cent), but the fatality rate very low. The type of illness was similar but the incubation period shorter, being only half to four hours, symptoms were severe but the course was rapid and the patient recovered in two or three days. The foods most commonly affected were canned meat, potted meat or fish, and milk products, more especially cakes and éclairs filled with cream or custard. Owing to the ubiquity of the organism our inability to distinguish toxic from non toxic strains and our comparative ignorance of conditions suitable for the production of toxins, outbreaks of poisoning of this kind were not only difficult to investigate but also harder to control.

The subject of milk was discussed from the point of view of the producer by Dr L. MEREDITH DAVIES (M.O.H. for Devon) and as it affects the consumer by Dr H. C. MAURICE WILLIAMS (M.O.H. for Southampton). Dr Davies dwelt particularly on the financial troubles of the farmer producing different types of milk. Here he thought lay the difficulty in obtaining a satisfactory milk supply, and until the margin of profit to the producer was considerably increased the bare essentials for the production of safe milk could not be realised.

CHILDREN

The MARCHIONESS OF READING, presiding over the section of women and children and public health, spoke on the 'pre school child.' She thought that all blocks of flats should be fitted with nurseries on the top floor or on the roof opening to a roof garden, or that children's homes should be attached to each block at which mothers could leave their children for short periods. She submitted that the combination of a day nursery and nursery school is the ideal provision, and referred to the many advantages of the large unit from the standpoint of cost and efficiency. Now that these were run on open air lines there was little risk of infections spreading among the children.

Colonel R. A. BRIDGEMAN read a paper on infant feeding in warm climates. He strongly advocated the use of sweetened condensed milk, as being stable, easily transported and not easily tampered with, and quoted many French authorities in support of this.

view. He also defended the use of cane-sugar in infant feeding.

Dr WILFRID SHELTON (physician in charge of the children's department King's College Hospital) speaking on diet and dietetic indiscretions after infancy dwelt more particularly on the period between the child's first and second birthday—the time he said when errors both of omission and commission are most likely. By the child's first birthday it should have abandoned the bottle and have its feeds at the times of the adult. He deprecated the giving of cream to any healthy child; the ingestion of more than one pint of milk daily was a mistake because it resulted in the refusal of other food. Dr Sheldon preferred cod liver oil to any of the vitamin A concentrates because it carries no risk of over dosage because it has a food value of its own and because it contains the complementary vitamin D.

In a discussion on the staffing of antenatal and infant welfare centres Dr C K J HAMILTON (physician in charge of the children's department, Charing Cross Hospital) envisaged the need of certain auxiliary services as essential to the ideal functioning of an infant welfare centre including a breast-feeding clinic, a play centre, and an observation ward. Dr VYCKE BORLAND (M.O.H. for Bethnal Green) said that the aim of the services was to make maternity as safe as possible and afterwards maintain good health in mother and child.

PREGNANCY TOXEMIA

Miss MARGARET BADSEN (gynaecological surgeon to the South London Hospital for Women) speaking on albuminuria and eclampsia quoted Prof F J Brown's finding that a blood pressure reading of over 130/70 is usually the earliest sign of toxæmia often preceding albuminuria by several weeks. She would treat all cases with readings of over 130 as suspect. While it was true generally speaking that the more the albumin the worse the case, the converse did not hold, for cases with only a trace might prove very severe. The risk in albuminuria was not only a risk of eclampsia but also a risk of permanent damage to the kidneys. Such damage depended not so much on the severity of the illness as on its duration and Miss Badsen recommended that toxæmia should never be allowed to continue for more than two or at most three weeks. As symptoms rarely appeared before the thirty-second week of pregnancy the only remaining treatment of an obstinate case—namely termination of pregnancy—did not necessarily mean the loss of the child. In any event the effect of the toxæmia is more damaging to the infant than the prematurity.

EARLY DIAGNOSIS OF CANCER

Dr ELIZABETH HURDON (director of the Marie Curie Hospital London) in a paper on the diagnosis of cancer in relation to its prevention said that in no other department of medical research had so much been discovered within recent years. It was probable that cancer did not arise in perfectly healthy tissue but in tissues or organs which had been the seat of pathological change. The list of chemical, bacteriological, mechanical or physical factors which operated as predisposing causes was being extended and the public needed to be educated to the importance of these factors, so that where necessary they would seek medical advice as to their removal. Dr Hurdon was hopeful of benefits accruing from statistical investigation pointing out that whereas the incidence of cancer of the non-exposed

site was the same in all social classes that of disease in the exposed sites—the skin, larynx and upper alimentary tract—showed considerable increase in incidence on descending the social scale. This suggested that other environmental conditions, such as defective hygiene might be responsible for the greater incidence among the poorer classes.

NUTRITION AND PHYSICAL TRAINING

In the absence of the president of the section of nutrition and physical training Sir STANLEY WOOD WALK (physician to Westminster Hospital) his address was read. He pointed out that just at the time that there was more leisure, there were more difficulties in the way of obtaining enough healthy physical exercise each day. While commending the national movement towards more and better physical training he urged that the aim should be a supple body with mind and muscle closely co-ordinated—a harmony of bodily function leading to perfect rhythm and balance. This meant that the body must be sufficiently nourished and he thought that attention should be paid to optimum rather than minimum diets. Sound nourishment however did not merely depend on a sufficient supply of food; there were many dietetic crimes such as the bolting of meals, inefficient cooking, the presentation of the same dishes with monotonous regularity and the belief that the most expensive food was necessarily the most nutritious weight for weight. Sir Stanley looked forward to the time when every housewife as a result of tuition at school will be able to buy food economically, cook it conservatively and well and serve it in well balanced physiologically adequate meals.

Prof S J COWELL (professor of dietetics in the University of London) said that though there was not much gross malnutrition in the sense of semi-starvation faulty diets were probably responsible for much more ill health and disease than was imagined only a few years ago. The problem of malnutrition in this country was much more a problem of deficiency in essential food constituents than of deficiency in total supply of food. He touched on the importance of the recently discovered tests for minor degrees of vitamin deficiency—vitamin A by impaired vision in dim light, vitamin B by its concentration in the blood; and vitamin C by its estimation in urine—and said that these should result in the detection of sub-optimal nutrition not apparent on clinical examination. He summarised the relation of nutrition to infection by suggesting that the course of certain chronic infections such as tuberculosis was related rather closely to the state of nutrition and that many acute infections especially in childhood, ran a more favourable course in those whose previous diet had been good. His conclusions on the relation of diet and dental decay were that diets rich in protective factors, given during the whole period of development of the teeth and continued throughout life would not only encourage the formation of sound teeth but would do much to prevent dental decay. There was increasing evidence that an inadequate supply of protective foodstuffs initiated or predisposed to some of the disturbances of pregnancy such as osteomalacia, muscular cramps and possibly some of the toxæmias. As a practical measure it was unnecessary to instruct the public in the exact amount of the various constituents of food required but they should get used to the term protective foods as being those that are rich in mineral elements and vitamins likely to be relatively deficient in common diets. They must learn that a good health giving diet should

contain a large proportion of its total energy value in the form of protective foods, the younger the person the greater being the proportion.

Miss E. M. WIDDOWSON (research biochemist at King's College Hospital) referred to the importance of the minerals in maintaining osmotic pressure and acid base balance, and in regulating all chemical processes. Of the fifteen different mineral elements in the body, each of which had its own part to play, deficiency was most commonly found in calcium, iron, phosphorus, and iodine, the two most often lacking in diets in this country being iron and calcium. To supplement calcium deficiency she advocated the greater use of cheese, milk, eggs, green leaf vegetables, and nuts, of these, milk was the most important single source. Iron was found mostly in meat (especially liver), eggs, brown bread, and green vegetables. There was often a deficiency of iron during pregnancy. It was important that it should be given in a form in which it would be available to the body.

TUBERCULOSIS

Dr R. A. YOUNG (consulting physician to the Middlessex Hospital) gave a presidential address to the section of tuberculosis. He spoke particularly of the need for early diagnosis and for teaching the laity to think bacteriologically. The undiagnosed case was dangerous to the community and he pleaded for the more thorough examination of all patients suffering from chronic bronchitis, from persistent cough and phlegm, from hæmoptysis however slight, from pleurisy or from unexplained loss of weight or condition, or evening tiredness. Clinical examination should be supplemented by bacteriological tests and radiography.

Dr F. G. CHANDLER (physician to St Bartholomew's Hospital) submitted that prolonged isolation of tuberculous patients was often unnecessary, they could return to their homes if they and their relatives understood how the disease was spread, the necessity for care of the cough and the phlegm, and of handkerchiefs, pillow slips, and sheets, and the importance of ventilation and fresh air.

Dr J. G. JOHNSTONE, speaking on tuberculosis of joints, said that the guiding principles in local treatment were to arrest the active disease, by stopping movement of the affected joint, and reduce the functional disability by immobilisation in the

correct position, and by preventing deformity in any other joint.

Dr L. L. SANDILAND (medical superintendent of the East Lancashire Tuberculosis Colony) dealt with the after care and re-employment of the tuberculous patient. The chronic tuberculous population could be divided into the 15 per cent of chronic invalids who would always remain a medical problem for others, the 50 per cent who could return to their former employment or some modified form of it, and the 35 per cent who could not return to their former employment either because it was unsuitable or because they could not compete with healthy men. The last group was the one for which after care schemes were intended. The three principal forms of provision made were workshops set up by after care committees or local authorities, the employment of ex-patients on the staffs of sanatoriums or similar institutions, and the establishment of village settlements, with industries attached, where the ex-sanatorium patient could have sheltered conditions, medical supervision, and a house away from his former habitation.

RHEUMATISM

The section on rheumatism and allied diseases met under the presidency of Sir ROBERT STANTON WOODS (physician in charge of the department of physical medicine at the London Hospital). Dr SYCLAR MILLER (medical director of the Harrogate Investigation Clinic) spoke on the etiology of chronic arthritis, and Dr DOUGLAS COLLINS (research fellow in rheumatism at the University of Leeds) referred particularly to the importance of trauma and infection as etiological factors. It was a mistake he thought to ignore the local condition of the joint while concentrating on the general physiological behaviour of the arthritic patient. Dr FORTESCUE FOX (president of the International League against Rheumatism) read a paper on "vicious spirals" in chronic rheumatism. Dr JOHN POYNTON (consulting physician to University College Hospital) opened a discussion on the etiology of rheumatism in children, and Sir FRANK FOX (organising secretary of the Empire Campaign against Rheumatism) summarised the history of the development of the movement. He pointed out that insufficient attention had been paid to rheumatism, in spite of the great suffering it caused, because it lacked the dramatic element.

PANEL AND CONTRACT PRACTICE

What is a Partner?

For health insurance purposes a partner must, as prescribed by Clause 11 (8) of the terms of service, be in the position of a principal in connexion with the practice and entitled to a share of the partnership profits which is not less than one third (in Scotland one half) of the share of any other partner. An insurance practitioner recently told an insurance committee that he had taken into partnership another practitioner. When asked whether the terms of the partnership agreement conformed to the requirements of Clause 11 (8) he said that his partner was not entitled to any stated share of the profits but was in receipt of a salary which together with certain allowances, amounted to a sum greater than one third share of the profits of the partnership. The Ministry of Health expressed the view that although there was nothing in the facts set out above which necessarily negatived the existence of a partnership it might be desirable for the insurance committee

to satisfy themselves as to the position by an examination of the deed of partnership if any. The practitioners were unwilling to submit the deed for examination, and the committee felt some hesitation in accepting the view that the salaried partner could be considered in the circumstances as entitled to a "share of the profits" and they asked for further advice. The Ministry took the view that the word "salary" implied the payment of a fixed sum payable out of the profits so long as the profits were sufficient to meet it. Presumably the committee would also have to be satisfied that provision had been made for the salary of the junior partner to be increased if the profits of the partnership should increase to such an extent as to make his present salary and allowances insufficient to comply with the terms of service.

Visitation of Surgeries

The Cheshire insurance committee have been trying to arrive at agreement with the panel committee about the visitation of surgeries. They

asked the panel committee to appoint members to meet an equivalent number of members of the insurance committee to consider and report upon the general question of surgery and waiting room accommodation, but the panel committee decided to take no action. The Ministry of Health was then asked what other course was open to the insurance committee to secure the provision by insurance practitioners of proper accommodation for their insured patients. The Ministry suggested that the panel committee would hardly withhold their co-operation in the event of any specific cases being brought to their notice where it appeared to the insurance

committee that there was ground for regarding the accommodation provided as unsatisfactory. And this proved to be the position. The secretary of the panel committee said that on a complaint being made they would be glad to co-operate but they had a strong objection to a roving commission to examine anybody's premises irrespective of complaints. After some discussion it was decided that any complaint as to the accommodation in a specific case brought in duly authenticated form to the notice of the insurance committee, should be investigated by a joint committee of the insurance committee and the panel committee.

GRAINS AND SCRUPLES

Under this heading appear week by week the unfettered thoughts of doctors in various occupations. Each contributor is responsible for the section for a month his name can be seen later in the half yearly index

FROM TWELFTH MAN

I

To sit in the pavilion while one's betters are battling can be a disintegrating experience. For a week past I have sat in the pavilion. I have re-read all the contributions to this Grains and Scruples series from the very lively knock with which West-country Practitioner opened the innings last July to the sound and stylish display by A Medical Economist. I have been amused, instructed, stimulated—and now when it is my turn to go in I am heartened by the knowledge that if Twelfth Man edges a lucky ball between first and second slip to the boundary there is a ripple of surprised applause.

These Grains and Scruples have indeed been surprising. Here are twelve doctors (and more apparently to come) who are willing to write from five to ten thousand words about a broomstick or nothing at all. There can I think be but one reason for this. Many doctors have an unsatisfied desire for self-expression. This is the modern explanation for ill behaviour in the nursery and it explains equally well these essays which have lightened for the last eleven months the pages of THE LANCET. That doctors lack self-expression is, I believe true. Our unhappy function is too often to listen and too often when we talk it is to use vain repetitions as the heathen do. If we are having a preliminary gossip—well there is the weather or the films and when we come to the real business of the patient's health how frequently we play the same record. I doubt whether the practice of a first-class physician equals in variety the practice of a leading counsellor. It does not elicit a comparable number of mental responses nor stimulate as complicated a series of conditioned reflexes. The physician for example whose practice has an abdominal bias will in a year see some hundreds of patients with an ulcer, an intestinal carcinoma or an abdominal neurosis. How often must these patients receive advice in much the same terms.

For the mutual convenience of physician and patient it is customary to have typewritten sheets of instructions for the victim's future regimen. At the end of a hurried interview with a physician a patient of mine was handed three such sheets. A guinea a sheet. Do I pay you directly or does the money go into the slot machine? asked my patient rudely.

And how stereotyped must the reactions of lesser men become. I sit at a bridge table with a fat lady as my partner and she asks: What is your call doctor? It is with difficulty that I refrain from replying: Three rye biscuits. Take one potato where three creep in. Eat as much of lean meat of green vegetables—

Next to me sits a successful business man. Your calling makes me giddy doctor. I want to reply.

Take it easy. Avoid stress and strain. John Hunter said he was at the mercy of any man who made him lose his temper. Live within the limits of your circulation. Grow old gracefully. Make your changes of posture slow and deliberate—

My readers if any will recognise these records. They are part of our common heritage. Hippocrates played them. So we go through our professional life with our small group of conditioned responses. How worrying and how annoying it is when a patient presents a group of symptoms and signs that refuse to fit into a syndrome. As difficult as it was for Pavlov's dog when his master altered the dinner bell by a semitone. Thus it is that our minds lack elasticity and our flow of ideas is constricted. Thus it is that A Departmental Doctor wrote: Regarded at any rate as an interesting companion as a desirable neighbour at dinner the doctor was ranked considerably below the barrister and a little more doubtfully lower than the priest. Thus it is that so many were glad to accept the invitation to contribute to the Grains and Scruples series. Here was a stimulating chance for unfettered self-expression.

This unsatisfied desire for self-expression may encourage the doctor off his guard into unwelcome confession to his patient. His wish to help the psychoneurotic may also lead him to confess a like frailty. I remember a dramatic instance of this. Many years ago a physician in the out-patient department of a large hospital was examining a boy in front of a class of students. He took the lad behind a screen and after a few minutes both emerged. The physician addressed the class: I thought so. The boy's a masturbator. The boy burst out: You sneak! You said you wouldn't tell and anyway you said you did it yourself when you were a boy. Confession may be obligatory in an Oxford Group meeting but such sharing is out of place in a consulting room.

It is doubtless necessary for these Grains and Scruples articles to be temporarily anonymous.

but it diminishes their "news value" Did not A Rover write that a newspaper proprietor would pay 2 hundred guineas for signed articles by medical men in the lay press but only five guineas if they were unsigned? And would not even the readers of THE LANCET have settled down in greater numbers to relish the incisive wit of A Rover had they known he was A in person, and enjoyed more keenly the urbanity of A Departmental Doctor had they known he was B and the author of C, and delighted more in the mild humour of A Doctor in Retirement if they had known he was D and the author of E and F? They would For who can lay his hand on his heart and deny that he brings a more lively expectation to sharpen the edge of his critical faculty when he knows himself to be looking at a Goya or a Vermeer? George Robey lifts an eyebrow and the house rocks with laughter, while the innominate comedian works desperately through a few painful moments for his first laugh Still anonymity has its advantages It seems possible that someone may glance down this page finding Twelfth Man a more attractive superscription than X, and I like to think that I could not have enjoyed more keenly the sanity and wisdom, the quintessential common sense, of A Rusticating Pathologist had I known who he was He described the town where I have lived happily for ten years as a place where the sun seldom shines and listed it, as an undesirable habitation, with Central Asia, Tierra del Fuego, Arctic Canada, and Orkney

* * *

It is difficult to guess to what extent the professional journalist welcomes and to what extent he resents the incursion of the amateur into his specialty I have no doubt that the office staff of THE LANCET could have written these Grains and Scruples a great deal better than have its invited guests The late Lord Salisbury described a popular daily paper at its inception as written by "office boys for office boys"! To day it may be written by impoverished politicians, gossiping peers, pamphleteering clerics, and pseudo scientists whose standards are no more worthy than their predecessors' the office boys Not that the amateur's contribution to journalism has been entirely without value The best things in the *Times* are Bernard Darwin's weekly article on golf (it might equally well be written on darts or tiddley-winks), the fourth leader and the correspondence columns No Saturday is completely ill spent that starts with Bernard Darwin Many a breakfast table has been rescued from disaster by the fourth leader What could add more relish to the eggs and bacon than to read Winston Churchill admonishing Lord Hugh Cecil, who had apparently expressed at one time or another disapproval of Italy, France, Japan, Nazi Germany, and Soviet Russia "It must be very painful to a man of Lord Hugh Cecil's natural benevolence and human charity to find so many of God's children wandering simultaneously so far astray In these circumstances I would venture to suggest to my noble friend, whose gifts and virtues I have all my life admired, that some further refinement is needed in the catholicity of his condemnations"?

Or Prof John Hilton's strictures on certain members of the House of Commons, "Yet it is not altogether a matter for mirth that elected persons should so eagerly allow themselves to be made the butt of informants defective in hearing wits or veracity A certain amount of silliness in public life adds to gaiety and does no harm But in excess it might spell our doom" There was a long correspondence

recently in the *Times* on the value of Family Prayers This dying habit received the most enthusiastic support from clerics and retired members of the services A long, wearisome, and occasionally painful experience of Family Prayers makes me certain that the day is better begun with Bernard Darwin, the fourth leader, and letters to the Editor

In parentheses, why is it that every strange sect, every exotic enthusiasm, every society of cranks draws its chief support from retired members of the services? Is it because these admirals and generals have grown tired of discipline and orthodoxy? Or because they have learnt that the secret of happy retirement is the espousal of a cause that is predetermined to be lost?

* * *

Medical journalism, like all trade journalism, is a different cup of tea Here a small group of professionals drives a team of ill assorted amateurs (If I had been the editor of THE LANCET I should have asked A Chronicler to have completed his fascinating history of medical journalism by telling of its present difficulties, its pitfalls, its humours, and its anxieties) The job of the professional is to invite, to cajole, and to flatter these "expert" contributors, and to edit, alter, improve, or refuse their contributions This is a difficult task Most of these experts would refuse with disdain the advice that a playwright accepts meekly from his stage manager They would retire in dudgeon if they had to endure the treatment that the scenario writer receives at the hands of the Hollywood producer or even the cutting that the copy of a working journalist gets from his editor They are thin skinned, hypersensitive, of an inordinate vanity This is the first difficulty of a medical editor Why does not the scenario writer withdraw his services when his work is mutilated? *Because he is well paid* I know nothing of the balance sheet of the weekly medical journals I know, however, that they have a circulation which compares favourably with the circulation of other weekly journals and they have access to an advertising field without rival Perhaps the only way for the editor to deal ruthlessly with his difficult team would be to pay them for their signed contributions

* * *

The second difficulty for the editor of a weekly medical journal must lie in the diverse interests of his readers There must be much for the general practitioner and physician but something too for those who practise a specialty Considering those difficulties weekly medical journalism maintains an extraordinary high standard It has one fault Like all other forms of journalism there is a great deal too much of it To be presented on Friday morning with a journal the equivalent in acreage of a full length novel and another of the same size on Saturday morning must overwhelm the leisure of the least busy doctor and fatigue the most receptive mind The individual articles are often of an incredible prolixity I find the clinicians generally more verbose than the laboratory workers The researchers produce reports that are often models of lucid brevity In a recent issue of THE LANCET Dr A Q Wells filled little more than a column with his exciting discovery of tuberculosis in field voles I tremble to think how some of us would have been tempted into an excess of "windy blether" on such an occasion We should have begun with accounts of the field mouse in literature (deliciously apt quotations from Robert Burns), the varieties of

field mice, and their habits and diseases proceeded to a discussion of the *Mycobacterium tuberculosis* its identity and methods of culture indicated in a few modest pages the implications the potentialities, and the cosmic significance of our discovery and rounded the whole thing off neatly with a verbatim report of the 134 post-mortems and some decorative micro photographs

I realise that it is not necessary for me to read anything that I do not wish to read and indeed it is common enough to hear a man say "Life's too short to read articles from start to finish" I only read the summary and conclusions. It is on behalf of the weaker brethren like myself that I cry mercy. We are not so strong minded nor so wisely economical of our time. Too often like a character of Aldous Huxley's, we creep from cover to cover like a beetle through dung.

I do not doubt that a living dog is better than a

dead lion but what if the lion being dead yet roareth? I was told by a neurologist that one of his prized possessions is an article by Hughlings Jackson on the different levels of humour—the lowest level dependent on incongruities of situation and the highest level that of organised wit. The whole thesis as the bookseller's catalogues say embellished with numerous illustrations. This may not be a subject of general medical interest but why should not the medical journals reprint selections from the works of Paré Lacanec Troussseau Addison Graves Gee Hughlings Jackson and Oeler? And even the 'Regimen Sanitatis of Salerno so beloved of Taddygaddy. They might be the beginnings of a liberal education for others besides myself.

There was a distinguished Victorian who said that every time a new book was published he turned back to read an old one. The idea is a sound one but difficult of execution in a day when new books like mugs are born every minute.

CORRESPONDENCE

DIAGNOSIS AND TREATMENT OF GASTRIC AND DUODENAL ULCER

To the Editor of THE LANCET

SIR,—In his paper published in your issue of May 22nd, Dr Duncan Leys makes a number of statements which ought not to be allowed to pass without criticism.

1. He says that gastric carcinoma is relatively uncommon. This is hardly the correct term to apply to a disease from which no less than 16 000 individuals die each year in Great Britain.

2. He suggests that the greater incidence of gastric than duodenal ulcers in his series of 58 cases represents the true facts and that all statistics showing a greater incidence of duodenal ulcer are incorrect because they are founded on surgical experience. My own series of 300 duodenal compared with 114 gastric ulcers at New Lodge Clinic and Prof. Ryle's of 583 to 131 seen in private prove how unfounded is this assumption. The difference between our statistics and those of Dr Leys is almost certainly a result of the difference in the social class of the patients, gastric ulcer being relatively much more common in hospital than in private practice. Thus whereas the relative incidence of duodenal ulcer and gastric ulcers in the comparatively well-to-do as calculated from our figures is 982 to 245 or 4 to 1 combined statistics from Guy's and St. Bartholomew's Hospitals give 875 duodenal to 1013 gastric ulcers.

3. There must be something radically wrong with Dr Leys's method of testing for occult blood. Using Dr Ryle's technique for the guinea reaction and the spectroscopic examination for hematuria and acid hematin the exclusion of blood and chlorophyll from the diet is essential as otherwise a positive result is almost always obtained. Occult blood is present in 100 per cent of cases of carcinoma of the stomach and in at least 95 per cent of gastric and duodenal ulcer in a large majority of cases it is still positive for several days after the disappearance of the niche seen with the X rays and its disappearance can be regarded as the most valuable evidence short of gastroscopy in the case of gastric ulcer of the persistence of an organic lesion.

4. Few physicians of experience would agree with Dr Leys that a patient with achlorhydria and longstanding indigestion whatever the age has gastric or duodenal ulcer. He has either chronic

gastritis or carcinoma. He certainly has not a duodenal ulcer and almost certainly not a gastric ulcer as we have never found achlorhydria in any of our 398 cases of duodenal ulcer and only once in our 114 cases of gastric ulcer at New Lodge Clinic in the single exception free acid returned after a short period of dieting which it would certainly not have done had carcinoma been present.

5. Though I have often protested against the excessive employment of surgery for gastric and duodenal ulcer I cannot but be amazed to read that "perforation remains the sole indication for surgical interference." I am Sir yours faithfully

ARTHUR F. HURST

New Lodge Clinic, Windsor Forest May 26th

SULPHÆMOGLOBINÆMIA AND METHÆMOGLOBINÆMIA AFTER SULPHANILAMIDE

To the Editor of THE LANCET

SIR,—Since making our communication on sulphæmoglobinæmia and methæmoglobinæmia following administration of p-aminobenzenesulphonamide (published in your issue of May 15th) a case has occurred in which methæmoglobinæmia and sulphæmoglobinæmia were found successively.

The case was one of septic abortion (cervical smear: non-hæmolytic streptococci) in a patient aged 33. No sulphates were given and she received 30 grammes of sulphanilamide in six equal doses during the 2nd and 3rd days after admission to hospital. By the evening of the 3rd day she was very anæmic and administration of the drug was stopped. Examination of the blood at this time revealed the presence of methæmoglobin only. The blood was again examined on the 6th day when sulphæmoglobin but no methæmoglobin was found. By this time cyanosis was slight but it persisted until the 16th day after admission. Administration of sulphanilamide was recommenced on the 8th day and continued until the 16th day but only in doses of 3 g. daily and in order to minimise the risk of aggravating the sulphæmoglobinæmia the lower bowel was frequently washed out with enemata. There was no apparent increase in cyanosis or sulphæmoglobinæmia after recommencing administration of the drug but the sulphæmoglobinæmia could be detected until the 20th day. The patient had received ten minims of acid, 10 drops dil. before each dose of sulphanilamide.

We believe that only one case of methæmoglobinæmia and sulphæmoglobinæmia in the same

patient has previously been recorded (R L Waterfield *Guy's Hosp Rep* 1928, 78, 265)

These findings support our conclusions regarding the relative persistence of methæmoglobin and sulphæmoglobin in the blood and our belief that giving hydrochloric acid may increase the liability of this drug to produce methæmoglobinæmia. The fact that in some cases slight sulphæmoglobinæmia occurs apart from administration of sulphur or its compounds does not disprove that sulphur has been responsible for many of the cases of sulphæmoglobinæmia recorded after giving sulphanilamide or other drugs. Rather does it emphasise that certain substances have an accelerating action on sulphæmoglobin formation (in vivo if not also in vitro) and that when such substances are being given as drugs a high concentration of sulphur in the alimentary tract should be avoided as far as possible both by excluding its administration and keeping the bowels open with non sulphur containing laxatives.

In examining the blood of the case herein described we have, of course, made all necessary tests to distinguish sulphæmoglobin from methæmoglobin. Sulphæmoglobin and methæmoglobin did not appear to be present simultaneously in the blood.

We are grateful to Dr Thomas Archibald of Belvidere Isolation Hospital for giving us facilities to investigate this case and those previously described.

We are, Sir, yours faithfully,

JAS C EATON,
J P J PATON

EXPERIMENTS ON THE ÆTIOLOGY OF LUNG TUMOURS

To the Editor of THE LANCET

SIR,—In the leading article in your last issue it is pointed out that the incidence of lung tumours in certain inbred strains of mice is increased by subcutaneous injection of carcinogenic agents—e.g., dibenzanthracene. You ask, "But why is the carcinogenic action of these substances focused on one organ—in this case the lungs?" I suggest that an extra stimulus comes from the external environment.

Some of my results—of prolonged dusting experiments with mice—which are being published next month, indicate that there may be an extra stimulus in the lungs—namely, some irritant or irritants inhaled in atmospheric dust. The lung is thus subject to constant irritation in this way even in ordinary atmospheres, but usually the degree of irritation is below the threshold. The subcutaneous injection of dibenzanthracene increases the susceptibility in certain strains so that the minor degrees of irritation may suffice to start the tumour in the lung. I am inclined to think that many of the earlier animal experiments with dust were of too short a duration, so that a reasonable conclusion could not possibly be attained. Lung tumours are usually late in development in mice as well as in man, where the mean age at death is 55 years.

I am, Sir, yours faithfully,

London N W, May 29th J ARGYLL CAMPBELL.

TREATMENT OF DRUG-ADDICTION

To the Editor of THE LANCET

SIR—In your issue of May 22nd Dr Vivian describes the use of autoserotherapy for drug addiction. I first made a note of this method when I read of it in a League of Nations publication about two years ago. It appeared to me that its results depended purely and simply upon the injection of serum, and

I therefore decided to test the effects of autolæmo therapy—i.e., the re injection of whole blood removed from the patient. My cases have been too few for publication, but the results in two of them were very striking. In a case of morphine addiction the patient had twice discharged herself from the hospital to which she had been admitted for this condition. She consulted me to obtain supplies, but since treatment two years ago, she has been completely free from craving. In a case of severe alcoholism sent to me by the probation officer of a police court the patient appears to have been cured, there has been no relapse for over a year. I have found a dose of 4 c cm adequate, and the best interval between doses seems to be four days.

I am, Sir, yours faithfully,

Camden road, N W May 31st H SEARLE BAKER

NŒVOID AMENTIA

To the Editor of THE LANCET

SIR,—In Mr Ralph Bates's interesting case of nœvoid amentia published in your last issue a radiogram of the skull is said to show irregular areas of calcification in the frontal region compatible with calcification in a plexiform angioma. Unfortunately little can be learned from the reproduction of the radiogram (Fig 2 of Mr Bates's paper) as to whether the shadow due to the calcification has the "festooned" appearance seen in other typical cases (compare the illustrations in the *Proceedings of the Royal Society of Medicine*, 1928-29, 22, 431).

Are plexiform angiomata in the frontal lobe more likely to be associated with amentia than others? There was no amentia in Dr C P Symonds's case (*loc cit*, p 440) in which the meningeal nœvus was mainly of the left occipital lobe. One would have thought that those on the right side of the brain, as in Mr Bates's case, would be less likely to be associated with amentia than those on the left side, but then in Mr Bates's case it is the frontal lobe which is chiefly involved. According to K H Krabbe (*Arch Neurol Psychiat*, Chicago, 1934, 22, 737) the intra cranial calcification is generally limited to the occipital lobe, according to H Bergstrand (*Abstracts of the Second Internat Neurol Congress*, London, 1935, p 124) and H Olivecrona (quoted in *Lancet*, 1936, 2, 752) röntgenological evidence of calcification is obtained in only a minority of cases, and in abortive forms epilepsy is often the only symptom.

I am, Sir, yours faithfully,

London W May 29th F PARKES WEBER.

PERNICIOUS ANÆMIA IN AN INFANT

To the Editor of THE LANCET

SIR,—Dr Smallwood's letter, in your issue of May 29th, does not contain the all important news as to whether or not any of his cases of subacute hæmolytic anæmia had histamine refractory achlorhydria. The case of pernicious anæmia in an infant, recorded by Langmead and Doniach, showed this feature, which, when taken in conjunction with the other findings, caused the infant's syndrome to resemble pernicious anæmia in every particular. The fact that the pernicious anæmia syndrome is almost unknown in infancy cannot alter the fact that when it does occur, it just does. Urinary obstruction due to prostatic disease is a condition peculiar to old men, I have seen it in a young child.

Dr Smallwood rightly states that achlorhydria is common in sick infants but this is not true when histamine is used to stimulate secretion of gastric juice, it has been sufficiently rare in my series of

cases always to raise in my mind the lurking suspicion that the nurse with more zeal than discretion has injected the histamine into the wrong baby or used a blocked needle. He is also right in saying that I do not call the megalocytic anemia of colonic disease pernicious anemia, surely he should know that no alumnus of the Birmingham Children's Hospital could be guilty of such an aberration.

INSULIN THERAPY IN MENTAL DISORDER

To the Editor of THE LANCET

SIR,—An Association of Insulin Therapists in Psychiatry has been formed with Dr G. W. B. James as president. The objects are to hold meetings to discuss all matters arising from insulin treatment, to catalogue and make available the international literature, and to discover by discussion and correspondence the most efficient foundations of prognosis and after care. The Association welcomes all workers in this method. I shall be able to answer any inquiries from those interested.

I am Sir yours faithfully

TRACHOMA IN REFUGEE CHILDREN

To the Editor of THE LANCET

SIR,—As president of the International Organisation against Trachoma, Mr A. P. MacCallan is clearly in a position to make ex-cathedra statements as to the dangers of introducing this disease into England and to warn the Ministry of Health against so doing. It is unfortunate however that before a question was asked in the House of Lords about the matter with its inevitable repercussions and alarms Mr MacCallan should not either have got in touch with any one of those directly concerned with the medical examination of the children or have made some inquiries as to the incidence of trachoma in the Basque district. He also appears to have assumed a trifle uncharitably that because the gentlemen who examined the children before embarkation in Bilbao were without special knowledge of ophthalmology they were therefore also lacking in the elements of common sense. We did, in fact, make it our first duty on arrival in Bilbao to inquire from the public health authorities as to the incidence of trachoma in the Basque district and found that of recent years it has been extremely low. This was confirmed by a Spanish ophthalmic surgeon of many years' experience in Bilbao who accompanied the children to England. Mr MacCallan's statements as to the high incidence of trachoma in certain provinces of Spain, apparently based on the report of the Consilium Ophthalmicum (1929 13 113) apply to the districts of Murcia, Almería, Valencia and Castellón. The suggestion however that trachoma is practically universal is so palpably exaggerated that it is surely based on a misunderstanding of Prof. Soria's statistics. The figure 90 per cent which he gives refers not to the incidence of trachoma in the population at large but to the percentage of eye cases which are trachomatous. Actually the highest incidence of trachoma in any province is 2 per cent of the population. The same source shows that the incidence in these districts was from 25 to 55 times as high as in the neighbourhood of Bilbao so that Mr MacCallan's

whole quotation is likely to be misleading. It is hardly realised in this country how widely different from South and South East Spain are the circumstances both as regards climate and public health in the Basque district. As to the further examination of the children Dr Richard Taylor (medical officer in charge of the Eastleigh camp) is replying to Mr MacCallan's letter in the *British Medical Journal*. Briefly each child who leaves the camp will have received a minimum of three full medical examinations. An ophthalmic surgeon with considerable experience in the diagnosis of trachoma sees all eye cases. No evidence of trachoma has been found in any instance.

We need hardly add that all those concerned are fully aware of their responsibility and most anxious to coöperate in necessary measures to prevent the spread of any infection that may occur.

We are Sir yours faithfully

RICHARD W. B. ELLIS

AUDREY E. RUSSELL

London W May 31st.

GASTRIC ACIDITY AND CHRONIC ALCOHOLISM

To the Editor of THE LANCET

SIR,—Would it not be in the interest of future generations to drop the phrase test-meal even if for some years more patients must submit to the meaningless ritual of gruel or alcohol? What evidence is there that the mechanism of secretion in man differs from that in experimental animals? Gruel, if introduced into the resting stomach in the small hours of the night without awakening the subject leads to no acid secretion. Seven per cent alcohol under the same circumstances usually also gives a small response only. In other words the test-meal response is not a response at all but is partly the result of a basal secretion which is either continuous (pathological) or conditioned by breakfast time and partly the result of various other conditioned reflexes.

The secretion of 100 c.c.m. of gastric juice per hour is quite sufficient to give a very high curve in a rapidly emptying stomach but it is no evidence that the patient is capable of secreting the 300 or 400 c.c.m. per hour needed to deal with the buffering powers of a Christmas dinner. The possessor of a normal mucous membrane even if he gives the lowly normal curve can reduce a protein meal to a low pH in a far shorter time than the patient with chronic gastritis who may incidentally give a hyperchlorhydric curve.

Chronic alcoholism and chronic gastritis are almost synonymous but the patients referred to in your annotation (May 20th p. 1292) were not given a fair trial. They had probably lost the habit of secreting at breakfast time and through their habit of drinking without food had lost the conditioned response to alcohol which better brought up persons tend to possess.—I am Sir yours faithfully

DEAN JENNINGS

BIPP TREATMENT OF ACUTE OSTEOMYELITIS

To the Editor of THE LANCET

SIR,—I should like to add my testimony to that of Mr J. H. Sant as to the great value of Bipp treatment in the prevention of necrosis after acute osteomyelitis.¹

Fifteen years ago a boy aged 6 was admitted to the East Suffolk Hospital with acute osteomyelitis of the left

¹ The case described here was reported in the *Clinical Journal* (1920 89 90).

leg of five days' duration. He was very ill with a temperature of 105° F and a pulse rate of 160. The leg was greatly swollen and inflamed and acutely tender. There was no effusion on the knee- and ankle joints. Thinking it possible that even when the periosteum was stripped from the shaft by pus and the medulla acutely infected, the actual structure of the dense bone might be still living and free from bacterial invasion, I decided to attempt complete sterilisation of the inner and outer walls of the shaft.

A tourniquet was applied above the knee. This is essential in order to keep the field of operation free from blood, and especially to avoid the danger of causing a general systemic infection by scrubbing the inflamed tissue during the operation. A long incision was made down the whole length of the diaphysis over the inner side of the tibia. The shaft was bare and bathed in pus, the periosteum being entirely stripped off. The pus was washed away and the surface of the bone and periosteum thoroughly cleansed by scrubbing with gauze, first with 1 in 20 carbolic lotion, then with spirit, and, finally, with ether. Sterile gauze was then packed between the bone and surrounding tissue, and the medullary canal laid open for its whole extent, the marrow which was infiltrated with pus was scraped away and the cavity scrubbed with carbolic lotion, spirit, and ether. The packing was then removed and a thick layer of gauze, moistened with carbolic lotion and soaked in Bipp (the excess of which was removed by squeezing), was laid between the bone and periosteum, and the medullary canal also packed with gauze soaked in Bipp. The usual dressing was then applied and the tourniquet removed.

On the next day the temperature and pulse were normal, the swelling had entirely subsided, and the leg was free from pain or tenderness. The gauze was removed on the third day. The wound healed quickly without suppuration except for a small sinus in the metaphysis at the head of the tibia which continued to discharge a little pus for several weeks. Finally a very small sequestrum came away at this spot and healing was complete. Unfortunately I did not realise at that time that the primary focus of infection in these cases is in the metaphysis. Had this focus been explored and sterilised, there would no doubt have been no delay in complete recovery.

I saw the boy five years later and took a photograph and radiogram of the leg. Both legs were of exactly the same size and shape, and the radiogram showed a perfectly normal shaft, except that the bone was solid throughout, the medullary canal being filled up.

I am, Sir, yours faithfully,

Worthing May 31st

HERBERT H. BROWN

OBSTETRICS IN GENERAL PRACTICE

To the Editor of THE LANCET

SIR,—The general opinion certainly is that the practice of obstetrics, like the practice of surgery, should be in the hands of those who have specialised in the subject. It is also desirable that in every area there should be a medical man readily available to attend to these cases, since many require attention at a very short notice. Our consulting surgeons usually reside in the larger towns and cities, this is quite satisfactory in the case of surgery, but would not be as satisfactory in the case of obstetrics. Further, many general practitioners are excellent obstetricians, keen on the work and (what is even more important) have the complete confidence of their patients. Certain of these practitioners might be given the care of the antenatal and confinement work in their area, but it would only be fair that they should produce some evidence to the authorities of their proficiency in the art of midwifery. The Diploma of the British College of Obstetricians and Gynaecologists and the Mastery of Midwifery of the Society of Apothecaries would either of them furnish good evidence of the special knowledge, but unfortunately

both these examining bodies require the candidates to have held resident appointments in hospital for at least six months before their examination. Now many quite able practitioners cannot afford to leave their practices for this length of time. Would it not be possible for some of our examining bodies to arrange an examination for a diploma in obstetrics, &c., without a compulsory resident appointment? If such an examination could be arranged in the very near future, practitioners desiring to specialise in the work would have reasonable opportunity to obtain that diploma before it is decided by the Ministry of Health to place the practice of obstetrics in the hands of experts.

I am, Sir, yours faithfully,

May 29th

SOALPEL.

METHODS OF DESTROYING BED-BUGS

To the Editor of THE LANCET

SIR,—Research on the eradication of bed bugs is being mainly (and rightly) directed towards discovering simple methods which are 100 per cent efficient. The "naphtha distillate" method described by Ashmore and McKenny Hughes (*Lancet*, Feb 27th, 1937, p 530) shows a real advance in technique, but as J M Holborn suggests in your issue of May 1st, there is still need for contact insecticides which can be used by the inhabitants of bug infested houses, insecticides which are cheap and easy to apply and whose use is not too obvious to the neighbours.

Experiments show that dilute methylated spirit kills bed bugs. A mixture of 30 parts of spirit with 70 parts of water has a low surface tension, so that it penetrates readily into the cracks which the insects inhabit. Practically every adult and nymph which the liquid touches dies, those in the cracks where the fluid remains for some time before it evaporates are all killed. Small nymphs are particularly susceptible, in fact this stage often dies if wetted with ordinary water. Eggs are more resistant than other stages, but eggs in the cracks which remain wet for an hour seldom survive.

This insecticide is very cheap, for if duty free spirit can be used the mixture costs about sixpence a gallon. It is not inflammable (50 per cent spirit kills eggs more readily, but is inflammable), it gives off no noxious fumes, and, most important of all, it does not damage furniture or bedding.

This method will not kill every bug in a house, but if the liquid is sprayed into the crevices few bugs will survive and the house will be made much more comfortable for the inhabitants. A second application after any eggs which escaped have hatched should leave almost none of the parasites alive. When fumigation and other methods have been perfected, this sort of treatment will not be necessary, but, until then, use should be made of any practicable means of alleviation.

I am, Sir, yours faithfully,

KENNETH MELLANBY

KING EDWARD'S HOSPITAL FUND FOR LONDON—A second series of coronation tours of places of interest in London is being held in aid of the Fund during June and July. Visits will be paid to the Tower of London, the Houses of Parliament, the Royal Naval College and the National Maritime Museum at Greenwich, Somerset House, Lloyds and Tilbury Docks. Further particulars may be had from the secretary of the Fund, 10, Old Jewry, London, E.C.2

OBITUARY

ALFRED ADLER, M.D Vienna

Prof Alfred Adler founder of the school of individual psychology arrived in Europe from America on April 26th with a very full programme planned for him. During the first month of his visit he gave nearly 50 lectures in Holland Belgium and France before coming to this country where his first public engagement was the delivery of a course of five lectures on psycho pathology at Aberdeen one on each day between May 24th and 28th. His last lecture on the 27th was on The Structure of Neurosis and was described by a member of a crowded and enthusiastic audience as one of the best Adler had ever been heard to give. Possibly the strain of his full European tour had overtaken his energies but he declared to a friend that he had found the work easy and was apparently in excellent spirits delighted with his welcome in Scotland, almost to the moment of his sudden death from heart failure on May 28th.

Alfred Adler was born in 1870 the second son of Leopold Adler and was educated at the Latin school and the University of Vienna, where he studied psychology and philosophy as well as medicine. He qualified in 1895 and worked in the Vienna General Hospital and Polyclinic from 1895 to 1897 when he set up as a general practitioner. He remained in Vienna for 30 years as physician and medical psychologist and during this long period passed through many phases of intellectual and emotional experience to become eventually the founder and leader of a school of thought which has taken hold in many countries.

Adler played a part in the recent history of psychotherapy that is not easy to assess. He was a practicing physician in Vienna when he became one of the small band of supporters whom Freud drew to himself after the period of isolation that followed his first enunciation of psychoanalytical principles. Adler however does not seem ever to have concerned himself with the technique of psychoanalysis but rather to have formulated general principles which he was able to apply to individual cases the chief being those of organ inferiority which led to the localisation of symptoms in the anatomically inferior organ and of the will to power which determined neurotic behaviour with its aim of influencing the environment and reaching a satisfaction not otherwise attainable the theory of the will to power giving to our language the much abused phrase inferiority complex. These formulations could not be reconciled with psychoanalytical principles and after vigorous controversy Adler was invited in 1911 to leave the Viennese Psychoanalytical Society. Since then he showed himself to be a vigorous propagandist and won support and popularity both in his own country and in England favoured by the absence from his teaching of any special emphasis upon sexual

causes of the psychoneuroses and also by the avoiding of the difficult conceptions associated with the theory of the unconscious. It was characteristic of Adler and his principles that he could expound them to an audience in a single lecture and convey the feeling that in them was a complete explanation of the pathological vagaries of human behaviour. His clinical methods were akin to the explanation and persuasion of Dejerme and his personal confidence and enthusiasm communicated itself to his patients as well as to his adherents. In this country he obtained more support from physicians and general practitioners than from professed psychotherapists, who admitted the usefulness of his approach but saw in it an over-simplification that might lead to the neglect of important mental processes outside his scheme of causes.

It was in 1912 the year after he had been asked to resign from the Viennese Psychoanalytical Society that Adler began to be specially interested in the prevention of neurosis and delinquency in childhood, an important branch of his interests which has probably received too little attention in this country. He began educating teachers to this end and gradually organised with collaborators child guidance centres in 30 schools in Vienna. It is reported by his admirers that these led to a remarkable decrease of delinquency in Vienna, until a change of educational policy resulted in their closure. His thesis was that it is the aim chosen in early childhood that decides the character of the individual. The trained individual psychologist seeks to reveal to a child what his aim really is and to enable him to change what is often a useless and egocentric attitude—likely to lead

towards a neurotic or delinquent future—to a social and cooperative attitude equally likely to lead towards a normal and successful life.

There has hardly been opportunity in this country to judge of the success of this teaching on a large scale but some who have watched Adler demonstrating his method with a child patient—such a demonstration had been arranged for the day of his death—are deeply impressed with its success.

During the last ten years America has been the seat of Adler's activities. He was appointed lecturer in Columbia University New York City in 1927 and though he went back to Vienna for a spell as clinical director of the Marienhiller Ambulatorium he returned to the United States as visiting professor at Long Island College in 1932. He wrote freely his most important works which have been translated (but not always very well) being on the study of organ inferiority the neurotic constitution and the practice and theory of individual psychology.

One of his three daughters Dr Alexandra Adler who is a research reader at Harvard, is now on her way to this country with the intention of carrying through her father's programme.

ARTHUR DOUGLAS HEATH, M D , F R C P Lond

Dr Douglas Heath, who died last month at Edgbaston, was consulting physician to the skin department of the Birmingham General Hospital and dermatologist to King Edward's Schools. Born in Exeter, the son of James Pulling Heath of Southernhay, he retained throughout life his interest in the west country, and just before his death had been present at the Devonian dinner. He was educated at Exeter Grammar School and University College, London, qualifying M B Lond. with honours in 1892 and taking the M D in the following year. After holding house appointments at University College Hospital, he settled in Birmingham, first in general practice in Edgbaston, then as assistant physician to the General Hospital, and as his interest in dermatology became more pronounced taking charge of the skin department and of the venereal clinic. In 1926 he presided over the British Association of Dermatology and Syphilology, and more recently was president of the Midland Medical Society.

"With the demise of Douglas Heath," writes a friend and colleague, "the Midlands have lost their acknowledged leader in dermatology. For a quarter of a century he taught at the General Hospital and in the University of Birmingham and many hundreds of students were first initiated into this rather puzzling speciality in Heath's inimitable manner. No one could forget his description, before a class of students, of such a condition as psoriasis or dermatitis herpetiformis, in a few words the salient points were brought out in a way very different from a text book description. The Birmingham medical school has lost a great teacher and a delightful personality."

Dr Heath married Annie, daughter of the Rev Henry Taylor of Wells, Somerset, and he leaves a widow with one son and one daughter.

EDWARD CARMICHAEL, M D , F R C P Edin

Dr Carmichael, who died on May 28th, at Bournemouth, where he was living in retirement, graduated at Edinburgh in 1884 and took the gold medal at the M D two years later when he was Syme surgical fellow. After being resident surgeon at the Edinburgh Royal Infirmary and tutor in clinical surgery at the University, he went into private practice in the city and became visiting medical officer to the City Poor House at Craglockhart. His successor writes of him: "With the passing of Edward Carmichael Edinburgh has lost one of her well known and greatly beloved physicians. For long years he faithfully guided and ministered to the members of a large general practice. He was a man wholly wrapped up in his work, ever ready for service both in bodily ailments and family distress. Nevertheless he found time to keep himself conversant with the advance of medicine, and those who worked with him will ever be grateful for his help and the knowledge gained through his great experience. Although he retired some years ago his old patients still talk and think of him as 'Edward the Beloved'. He was the ideal family doctor and friend." His son, Dr E. Arnold Carmichael, is director of the neurological research unit at the National Hospital, Queen-square.

EMILY FRANCES CAMPBELL, L R C P Edin

WE regret to announce the death on May 20th of Lady Campbell, widow of Sir John Campbell, the

distinguished Belfast surgeon. Lady Campbell was daughter of the Rev William Chestnut, of Traler, Co Kerry, and received her early education at the Victoria College, Belfast. She was first married to Dr Fitzsimons, a medical missionary, with whom she worked abroad for some years. After his death she decided to return to Belfast and study medicine. She took her degrees at Edinburgh and afterwards engaged in private practice in Belfast, on the Antrim road until her marriage to Sir John Campbell some three years later. During his lifetime Lady Campbell identified herself closely with her husband's work, acting as his anaesthetist and taking a deep interest in the welfare of the Samaritan and other Belfast hospitals. Of attractive personality she was everywhere respected for her kindly and gentle disposition. She is survived by two sons, the elder, Robert, a graduate in agriculture of Cambridge University, the younger, William Stewart, a recent graduate in medicine of Queen's University, and a demonstrator in the Belfast Medical School.

Dr GEORGE HAMILTON WINCH, who has died at Penarth, at the age of 58 years, was for sixteen years specialist officer in the treatment of venereal diseases under the Glamorgan County Council. He qualified M B Edin in 1904, taking honours in anatomy and surgery, was then house physician and pathologist at the City of London Hospital and later assistant medical officer of Oxford County Asylum. During the late war he was bacteriologist to the Northern Command with the rank of Captain R.A.M.C. He is survived by his widow and two daughters.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED
MAY 22ND, 1937

Notifications—The following cases of infectious disease were notified during the week. Small pox, 0, scarlet fever, 1525, diphtheria, 850, enteric fever, 20, pneumonia (primary or influenzal) 787, puerperal fever, 32, puerperal pyrexia, 114, cerebrospinal fever, 23, acute poliomyelitis, 3, acute polio encephalitis, 2, encephalitis lethargica, 5, dysentery, 14, ophthalmia neonatorum, 116. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 28th was 2948 which included: Scarlet fever 748, diphtheria, 841, measles 68, whooping-cough 494, puerperal fever 22 mothers (plus 15 babies), encephalitis lethargica 282, poliomyelitis 1. At St Margaret's Hospital there were 22 babies (plus 16 mothers) with ophthalmia neonatorum.

Deaths—In 123 great towns, including London, there was no death from small pox. 1 (1) from enteric fever, 10 (1) from measles, 1 (0) from scarlet fever, 14 (4) from whooping-cough, 20 (5) from diphtheria, 47 (0) from diarrhoea and enteritis under two years, and 34 (1) from influenza. The figures in parentheses are those for London itself.

Hull reported 3 deaths from measles. Middlesbrough and Birmingham each 2. There were 7 fatal cases of diarrhoea at Liverpool 4 at Birmingham 3 at Nottingham.

The number of stillbirths notified during the week was 275 (corresponding to a rate of 40 per 1000 total births), including 43 in London.

NEW HEALTH CENTRE AT ISLEWORTH—Sir George Newnam has opened a health centre at Busch-corner Isleworth. There is a large central hall for lectures and demonstrations capable of division into separate waiting-rooms and a dental wing, arranged as an independent unit. The building cost £7610.

PARLIAMENTARY INTELLIGENCE

FACTORIES BILL COMMITTEE STAGE CONCLUDED

THE Factories Bill was further considered by a standing committee of the House of Commons on May 25th and 27th.

INTERPRETATION OF FACTORY

On Clause 144 Mr. SHORR moved an amendment to provide that premises where switching operations were performed should be brought within the Bill. In 1935 there were 47 accidents in stations above 600 volts and 92 accidents in stations below 600 volts.—Mr. GEOFFREY LLOYD said the Electricity Commissioners had a statutory responsibility for securing the safety of the public and they were advised that that included their employees. But the Home Office would take up the matter again with the commissioners.—On this understanding the amendment was withdrawn.

DEFINITION OF YOUNG PERSON

On Clause 145 Sir J. SIMON, Home Secretary, secured amendments to make the definition of a young person read: A person who has attained the age of 14 and has not attained the age of 18 but does not include any person whose parent is required under or by virtue of the Education Acts 1921 to 1937 to cause him (unless there is some reasonable excuse) to attend school or to attend an alternative course within the meaning of the Education Act 1936. No one ever intended that young persons who were required to be kept at school should be available for factory work, and it was better to say so in the Bill in proper terms.

On Clause 148 Mr. T. M. COOPER, Lord Advocate, secured a similar amendment for Scotland and another making it unnecessary to hold an inquiry under the Fatal Accidents Inquiry (Scotland) Act of 1895 in any case where the Home Secretary had already held an inquiry.

WORKING HOURS FOR YOUNG PERSONS EMPLOYED IN FACTORIES

Sir J. SIMON moved the following new clause:—

(1) Subject to the provisions of this section as from the expiration of a period of two years after the commencement of this Act, the foregoing provision of this Part of this Act limiting the hours worked in any week exclusive of intervals allowed for meals and rest shall have effect in the case of young persons who have not attained the age of sixteen as if for the reference to forty-eight hours there were substituted a reference to forty-four hours.

(2) If representations are made to the Secretary of State with respect to any class or description of factory—

(a) that the industry carried on in that class or description of factory is, either generally or as respects a particular process, so dependent on the employment of such young persons and so organised that the carrying on of the industry would be seriously prejudiced unless the number of hours worked in a week by such young persons employed in that industry or in that process were permitted to exceed forty-four;

(b) that such increased hours would not be likely to be injurious to the health of the young persons; and

(c) that the work in which the young persons would be employed in that industry or process is particularly suitable for young persons and that their employment would familiarise them with and help to train them for employment in processes in which older persons are employed in the industry and be likely to lead to their permanent employment in the industry.

The Secretary of State may direct an inquiry to be held and, as a result of the inquiry, he is satisfied with respect to all the matters aforesaid, he may make regulations increasing the total hours exclusive of intervals allowed for meals and rest that may be worked by such young persons in any week in that class or description of factory

or as the case may be in a particular process carried on therein to such figure not exceeding forty-eight as may be specified in the regulations.

The committee were he thought all of one mind in wanting to devise some plan which would not leave 48 hours for young persons under 16 as the permanent provision of the Bill. This new clause had been brought forward to fulfil as far as possible that object. But if they were to make a reduction it could not be done merely by a stroke of the pen. There must be a suitable interval provided and the new clause provided that the interval should be a period of two years from the commencement of the Act. The new clause was the result of very careful inquiry in which the Home Office had had the help of trade-union leaders and employers' representatives.

Viscountess ASTOR said she was astonished that the Government at this time of day proposed to allow children under 16 to work 44 hours a week in factories.—Sir E. GRAHAM LITTLE said he was certain that if the committee pressed for a 40 hour limit it would carry public opinion with it.—Mr. LLOYD replied that in this matter they had to secure a practical compromise between what should be done for the children and what were the needs of industry. The absence of juveniles might very seriously affect the output and it might be the wages of the adult workers.—Mr. RHYE DAVIES secured an amendment to make the interval after the passing of the Act before the clause came into operation one instead of two years, but his further amendment to reduce the number of hours work per week for juveniles in factories from 44 to 40 was negatived by 20 votes to 10.

Mr. LLOYD moved that a young person who works in a factory whether for wages or not in collecting, carrying or delivering goods, carrying messages, or running errands shall be deemed to be employed in the factory for the purposes of this Act; provided that the provisions of Part VI shall not apply except as expressly provided, to any such young person who is employed mainly outside the factory. This was agreed to.

WORKING HOURS FOR YOUNG PERSONS EMPLOYED OUTSIDE FACTORIES

Mr. LLOYD moved a new clause defining the conditions of employment of young persons employed in the business of a factory wholly or mainly outside the factory:

(a) The total hours worked exclusive of intervals allowed for meals and rest shall subject to the provisions hereinafter contained relating to overtime not exceed forty-eight in any week.

(b) The young person shall not be employed continuously for a spell of more than five hours without an interval of at least half an hour for a meal or rest and where the hours of employment include the hours from half past eleven in the morning to half past two in the afternoon an interval of not less than three-quarters of an hour shall be allowed between these hours for dinner.

(c) On at least one week-day in each week the young person shall not be employed after 1.30 p.m.

(d) The young person if he has attained the age of sixteen may on occasions of seasonal or other special pressure or in cases of emergency work overtime that is to say in excess of the permitted weekly hours but his hours of overtime work shall not exceed six in any week or fifty in any calendar year and where any employer has employed overtime any young persons to whom this section applies in twelve weeks (whether consecutive or not) in any calendar year neither he nor any person succeeding to his business shall employ young persons to whom this section applies overtime during the remainder of that year.

(e) The young person shall in every period of twenty-four hours between mid-day on one day and mid-day on the next day be allowed an interval of at least eleven

consecutive hours which shall include the hours from 10 o'clock in the evening until 6 o'clock in the morning

Sir E GRAHAM-LITTLE protested against the five hours' continuous spell provided in Sub-section (b) and the 13 hours in Sub-section (c) which he said he considered to be too long—Viscountess ASTOR concurred

WORK BEFORE AND AFTER CONFINEMENT

Mr GRAHAM WHITE moved the following new clause—

Any woman or young person employed in a factory shall be entitled, on the production of a medical certificate stating that her confinement will probably take place within six weeks, to leave her work, and she shall not be permitted to work during the six weeks following her confinement

Any woman or young person who shall have left her work under the provisions of this section shall be entitled to be re-employed at the end of the period of rest

He would like, he said, this country to come into line with the legislation and practice of foreign countries

Sir E GRAHAM-LITTLE said that he hoped the Committee would not accept the new clause. Any hard and fast rules for the treatment of confinements before and after delivery were entirely unscientific. Every case should be judged on its merits. The whole question was dealt with in a more sensible way in the munition factories during the late war when graded work was found for women during the pregnancy period.

Viscountess ASTOR said the new clause, if adopted, would do a great disservice to women. From the point of view of the State it would be very wise on the part of the Government to say that a woman could apply for exemption a month, say, before the child's birth as well as a month afterwards, provided she had full maternity benefit. Sooner or later we must do something to protect women who went into industry so that they should have full time for child bearing.

Mr RHYS DAVIES agreed with Lady Astor. Maternity benefit had not had the effect people imagined it would. The women complained that most of the money did not go to them to buy food and clothing but to the people in the professions who worked on them. He was satisfied that women in industry who bore children ought to receive very much more consideration from the community than they did.

Mr R S HUDSON, Parliamentary Secretary to the Ministry of Health, asked the Committee not to accept the clause for several reasons. It was a clause appropriate not to a Factories Bill but to a Public Health Bill. Secondly, it attempted to put into force part of a provision included in the draft Washington Convention. Actually this was made dependent on the provision that when a woman left work in these circumstances she was to receive full and adequate maintenance. He agreed with Lady Astor that without the provisions of the Washington Convention this clause would do much more harm than good. At present any woman who could get a doctor's certificate to say that she was incapable of work was entitled to sign off and receive benefit for four weeks before the confinement, and no employer was allowed knowingly to employ a woman within a certain period after the date of confinement.

The clause was negatived without a division.

PROVISION FOR NURSING MOTHERS

Mr GRAHAM WHITE moved another new clause—

A woman or young person employed in a factory who is nursing her child shall be allowed half an hour twice a day for this purpose, and time so allowed shall be included in the calculation of the total hours worked.

Mr HUDSON said he was afraid that he would again have to ask the Committee not to accept this clause,

because it was not in any way complete. In order to be effective it would also have to include provisions for insisting that factories should provide nurseries, or rooms where the mother could nurse her children, and some arrangement for bringing the children from the home to the factory. They were informed by their scientific advisers that in these times of a much shorter working day provisions of this nature were unnecessary, that it was sufficient in normal conditions for a woman to nurse her baby before she left for the factory and immediately after she got home, and that provision for one artificial meal for a child in the middle of the working period was a much better arrangement than either expecting the woman to go back home to nurse the child or arranging for the child to be brought to the factory.

The clause was negatived without a division.

YOUNG PERSONS AND DANGEROUS MACHINES

Colonel SANDEMAN ALLEN moved a new clause dealing with the training and supervision of young persons working at dangerous machines. He said that he was not satisfied that in the case of young persons there was at present sufficient supervision or that the powers of the Home Secretary were altogether adequate. The figures for accidents to young persons had increased in the most alarming way—Mr LLOYD said that the Government were prepared to accept the clause.

The Committee stage being concluded, the Bill, as amended, was ordered to be reported to the House.

NOTES ON CURRENT TOPICS

Eradication of Animal Diseases

In the House of Commons on May 27th Mr W S MORRISON, Minister of Agriculture, made a statement on agricultural policy, in the course of which he said that the Government proposed to initiate a large scale and more comprehensive campaign for the eradication of animal diseases in Great Britain. Their object was to improve the health of livestock and increase agricultural productivity by seeking to eliminate what was perhaps the worst of all forms of wastage and economic loss in agriculture. In the first instance, efforts would mainly be directed to the eradication of diseases among cattle. The scheme would involve an additional charge on the Exchequer of about £800,000 per annum for the first four years. It would, however, involve centralisation of public veterinary services and as against the increased cost to the Exchequer, the expenditure by local authorities would be reduced by about £170,000. Parliamentary authority would be required for these proposals. The Government were anxious, however, to lose no time in developing the existing schemes of control of disease and accordingly he was arranging at once to amend the Attested Herds Scheme under the Milk Act, 1934, by providing additional assistance in England and Wales, as had already been done in Scotland, to owners of dairy stock who were desirous of eradicating tuberculosis from their herds. This revised scheme would become operative on June 1st next. In the opinion of the Government the proposals which he had outlined by increasing the productivity of our agriculture, not only would enable it better to meet the situation in the event of war, but would be a substantial aid towards raising efficiency, lowering costs and establishing the industry on a sounder economic foundation in time of peace. The necessary legislation to give effect to these proposals would be introduced at the earliest possible moment.

Trade Marks and Proprietary Preparations

In the House of Commons on May 27th Dr BURGESS (then Parliamentary Secretary to the Board of Trade) moved the second reading of the Trade Marks (Amendment) Bill, which has already passed through the House of Lords. He said that the Bill generally speaking, implemented the report of the Departmental Committee which had reviewed the law

relating to trade marks. Clause 4, which was the main clause of the Bill dealt with words used as the name or description of an article and would be of assistance to owners of well known trade marks.

Mr A. V. ALEXANDER, in moving the rejection of the Bill, said that under the measure if it was not amended trade mark infringement would occur if any one made any reference to other goods which they were selling under a mark. For example it would be impossible to sell a medicine as similar to "although in effect the two productions might be identically made of common substance in which there was no special virtue. The only virtue was in the use of the adopted trade mark which might perhaps lead to an exploitation of the public in price which was absolutely indefensible.

Mr BARNES said that in many cases owners of proprietary preparations were taking advantage of the present legal protection to practise frauds on the public in the claims they made regarding the curative powers of their preparations and the prices they charged for them. Safeguards which were very essential for the protection of the public at large, ought to be inserted in the Bill and obligations imposed on the owners of proprietary preparations which would prevent them from exploiting the public. There ought not to be, as a result of the Bill further restrictions in the realm of proprietary goods.

Mr BROAD expressed the fear that some of the provisions of the Bill would have the effect of enabling people to build up a little preserve or monopoly. He had a case in mind. Some chemical firms were selling a new and very valuable kind of disinfectant, for use as a gargle and so on. It was called 'Thymol' and to make it ready for use it was compounded in some way with glycerine. Prescriptions were given by doctors to be taken to the chemist for this glycerine of thymol. It became more generally used, and then a very big American firm put up the stuff as a standard article and called it glyco-thymoline. Other firms began to do the same thing calling it glycerinated thymol or glycerine of thymol. Since glycerine of thymol or glycerinated thymol sounded very like glyco-thymoline, it might be said that one could never sell glycerine in combination with thymol because of the trade mark glyco-thymoline. He was afraid of the creation of monopolies in that way.

Dr BURGIN, replying to the debate said defensive trade marks were never to be invented. There would therefore, never be any prohibition on members of the public using simple language and descriptions of articles by their proper names. If Clause 15 could really be thought to extend to the verbal boost by a salesman that a certain thing was in his opinion as good as or equivalent to aspirin then that was nonsense. If it was necessary to delete or insert words to prevent that impression gaining ground, it could be done in committee. There was a whole series of things in regard to which a manufacturer ought to be able to attach conditions such as the packing stoppering &c of his goods. The idea was that the manufacturer when an article left his factory in a particular state should if the customer required it in a particular state be entitled to say that it should reach the customer in that state.

The motion for the rejection was withdrawn and the Bill was read a second time.

In the House of Lords on May 25th the Widows Orphans and Old Age Contributory Pensions (Voluntary Contributors) Bill was read a second time. The Children and Young Persons (Scotland) Bill was read the third time and passed.

In the House of Commons on May 27th, the Public Health (Drainage of Trade Premises) Bill which has already passed through the House of Lords, was read a second time.

In the House of Commons on May 28th the Marriage Bill was read the third time by 190 votes to 87.

QUESTION TIME

WEDNESDAY MAY 26TH

Approved Societies

Mr PARKER asked the Minister of Health whether in view of the differing practices of various approved societies in the administration of the National Health Insurance Act he was prepared to secure the introduction of a uniform system under which the rights of insured persons to benefit were more clearly defined.—Mr HUDSON, Parliamentary Secretary to the Ministry of Health replied: My right hon. friend has no reason to think that under the system of administration of national health insurance through approved societies insured persons are not aware of their rights to the benefits provided by the Act and as every insured person has a right of appeal if he is dissatisfied with the decision of his society on a claim for benefit my right hon. friend does not consider that any such fundamental change as is suggested by the hon. Member is either necessary or desirable.

Mr RHYE DAVIES asked the Minister of Health in connexion with the freedom of choice of approved society the approximate total membership of the few approved societies which had agreed not to accept applications for transfer from members of certain other societies the group of societies to which they mainly belonged and the approximate percentage such membership bore to the total membership of approved societies.—Sir KINGSLEY WOOD replied: Approved societies entering into arrangements of the kind referred to by the hon. Member are not required to notify such arrangements to my department and do not in fact do so. I am not therefore in possession of the information asked for in the question.

THURSDAY MAY 27TH

Survey of Working-class Budgets

Mr TOM SWINN asked the Minister of Labour whether the inquiry into the question of the revision of the cost of living index figure was yet completed and if so what action he proposed to take.—Mr KENNETH BROWN replied: The methods to be adopted in obtaining the data required for a revision of the basis of the cost-of-living index figures have for some time been under consideration by my department in consultation with an advisory committee appointed for this purpose. The committee have recommended that budgets should be collected giving details of the expenditure of a representative sample of some thousands of working-class families in each of four weeks at quarterly intervals beginning in the autumn of this year and the necessary preparations for the collection of these budgets are now being made.

Tuberculosis in Wales

Mr JAMES GRIFFITHS asked the Minister of Health having regard to the high mortality rate from tuberculosis in Wales, what steps he proposed to take to deal with the problem. In particular what progress was being made with proposals for rural housing and whether these plans could be expedited in view of the gravity of the problem.—Sir KINGSLEY WOOD replied: Although the rate of mortality from tuberculosis in Wales is higher than in England and Wales as a whole I may remind the hon. Member that there has been a substantial decline in the rate in Wales as well as in the rest of the country this decline amounting to 38 per cent on the figures for 1935 as compared with 1910. In Wales the arrangements for the treatment of tuberculosis are made by the Welsh National Memorial Association on behalf of the Welsh County and County Borough Councils and a survey of the services provided by the Association is at present being undertaken by one of the Medical Officers of the Welsh Board of Health. I am awaiting the results of this survey before considering what further measures are required. As regards the second part of the question, the position is that 4300 houses are included in the slum clearance programme of the Welsh rural authorities and that 1339 replacement houses have been approved of which over 700 have been completed. A further 388 houses have been approved for the abatement of overcrowding and for general needs. My department is continually

watching the progress of the clearance programme with a view to expediting it where possible

Committee on Corporal Punishment

Mr MUFF asked the Home Secretary whether he was now in a position to announce the constitution of the committee on corporal punishment.—Sir J SIMON replied: At the suggestion of my right hon. friend, the Secretary of State for Scotland, it has been decided that the committee shall inquire not only into the English but also into the Scottish law and practice. The committee's terms of reference will be "To consider the question of corporal punishment in the penal systems of England and Wales and of Scotland, to review the law and practice relating to the use of this method of punishment by Juvenile Courts, by other courts and as a penalty for certain offences committed by prisoners, and to report what changes are necessary or desirable." As already announced, the Hon. Edward Cadogan has consented to act as chairman of the committee. The following ladies and gentlemen have now accepted invitations to serve on it: The Lady Amptill, C.I., G.B.E., Mrs A. E. Astley, Prof J. E. Brierly, O.B.E., J.P., Mr E. Ford Duncannon, D.S.C. M.A., J.P., Dr Robert Hutchison, Sir William McKechnie, K.B.E., C.B., Mr H. R. Tutt, and Mr Cecil Whiteley, K.C. My right hon. friend and I contemplate adding one other woman member, whose name will be announced as soon as possible.

Duke-Fingard Treatment of Respiratory Disease

Mr ROWSON asked the Minister of Health if he would set up a committee of inquiry, consisting of an equal number of medical men and laymen, to inquire into the efficacy and genuineness of the Duke-Fingard inhalation treatment for diseases of the respiratory organs, such as chronic catarrh, bronchitis, bronchiectasis, asthma, and tuberculosis, and if he would take steps to have this treatment made available for panel patients under the Health Insurance Acts who were suffering from chest complaints.—Sir KINGSLEY WOOD replied: No, Sir. I am not aware of any sufficient reason for instituting a special inquiry into this treatment. As regards the second part of the question, an insurance practitioner is free to give such treatment as in his judgment is appropriate for his patients.

Watered Milk

Mr DAVID ADAMS asked the Minister of Health whether he had now decided to take further steps to protect the public against watered milk, in view of the failures in recent prosecutions in cases of proved watering to obtain convictions before the magistrates.—Sir KINGSLEY WOOD replied: I have considered this matter again in the light of the recent prosecutions to which the hon. Member drew my attention. I understand that there was conflicting evidence in these cases, and that the magistrates in their discretion decided not to convict. In these circumstances, I do not as at present advised propose to introduce any fresh legislation on this subject.

Admission of Foreign Doctors and Dentists

Mr ROSTON DUCKWORTH asked the Home Secretary what was the present policy of his department with regard to the admission into this country of foreign doctors, dentists, research workers, and students, whether he could give the aggregate number permitted to settle here in the last two years, and what representations he had received from professional bodies in this country on the subject of this form of competition.—Mr GEOFFREY LLOYD, Under Secretary, Home Office, replied: The policy is to restrict closely the admission of foreign doctors and dentists who wish to set up in practice in this country after being admitted to the British Medical and Dentists Registers. Since March, 1935, the rule has been not to permit foreigners to engage in medical practice in the United Kingdom save in the most exceptional circumstances: the same rule has been applied in the case of foreign dentists since February, 1936. No general figures of the numbers to whom permission to practice has been granted are available. The question of the admission of refugee doctors and dentists from Germany has been the

subject of representations from and discussion with the various professional bodies concerned and separate figures have been kept of the numbers of refugee doctors and dentists to whom permission to set up in practice has been granted. They are 183 doctors and 78 dentists, of whom the large majority, in the case of the doctors, had either been granted permission to practise or had commenced their studies for a British degree before March, 1935, and in the case of the dentists had been admitted to the Dentists Register before February, 1936. As regards research workers and students whose work does not involve employment in the service of a person or firm in this country, no obstacles are placed in the way of their admission provided their maintenance here is assured, but they are expected to leave on the completion of their research or study. If employment is involved they are not admitted unless in possession of a permit issued by the Minister of Labour to their prospective employer in accordance with Article 1 (3) (b) of the Aliens Order, 1920.

MONDAY, MAY 31ST

Spanish Refugee Children and Public Assistance

Mr MESSER asked the Minister of Health if he was prepared to sanction public assistance committees providing accommodation for Spanish refugee children in homes or institutions at public expense.—Mr BERNAYS, Parliamentary Secretary to the Ministry of Health, replied: As financial responsibility for the Spanish refugee children has been undertaken by a number of voluntary bodies, my right hon. friend is not prepared to sanction expenditure on their maintenance by local authorities from public funds.

Ventilation of Telephone Kiosks

Sir MURRAY SUETER asked the Postmaster General whether any recent experiments had been conducted in connexion with ventilating public telephone kiosks in constant use, and whether some simple ventilation contrivance could be devised and, if satisfactory adopted, in the interests of public comfort and health, in positions where a 100 per cent noise proof telephone kiosk was not necessary.—Major TRYON replied: If the question refers to kiosks in the open, of which practically all are necessarily on or near the highway, my information is that the noise problem is far more important than that of ventilation. If, however, the question refers to cabinets indoors, I can assure my hon. and gallant friend that the question of improvement in ventilation is being actively pursued.

Compensation for Silicosis

Mr JAMES GRIFFITHS asked the Home Secretary if he was aware that the South Wales Coalowners Indemnity Society were refusing to pay compensation to men certified by the medical board to be disabled by silicosis, that the reason given for this refusal was that the society proposed to institute proceedings for the purpose of seeking a declaration that the silicosis orders issued by him were ultra vires, and that meantime these men were compelled to seek public assistance, and what action he proposed to take in the matter.—Sir SAMUEL HOAR replied: I have no information to the effect suggested in the question. I should be prepared to consider any fuller particulars which the hon. Member may send me, but I have, of course, no power to interfere with any legal proceedings.

Mr GRIFFITHS asked if Sir Samuel Hoar did not consider it deplorable that employers should try to take advantage of some possible technical flaw to deprive men suffering from this disease of compensation, and if he would give an assurance, if the courts held that this order was ultra vires, that these men would not be penalised but that the Government would bring in a new order to give them the compensation to which they were entitled?

Sir SAMUEL HOAR said he agreed that this was a matter of great importance, but he would rather not express an opinion until he had further facts.

ROYAL SOCIETY OF ARTS.—The Albert medal of this society for 1937 has been awarded to Lord Nuffield for services to industry, transport, and medical science.

PUBLIC HEALTH

The Bournemouth Outbreak of Enteric Fever

THE official report on the outbreak of enteric fever in Bournemouth Poole and Christchurch last summer has now appeared,¹ and proves to be well worth waiting for. In his explicit prefatory note Sir Arthur MacNalty refers to the certainty that raw milk was the vehicle of infection and to the strong probability that the retailers' bulk supply was infected by a relatively small contribution, itself produced without apparent fault. How the milk became infected is not actually proved but the late Dr Vernon Shaw who compiled the report now published gives sound reasons for assuming a connexion between this outbreak and a particular carrier. The sequence of events was as follows.

On August 21st the Ministry of Health received a telegram from the medical officer of health for Poole who reported a notification of a case of enteric fever stated that he had reason to believe others might occur and asked for assistance. An hour later a telegram was received from the deputy medical officer of health for Bournemouth reporting some cases of suspected food poisoning enteric type and also asking for assistance.

Dr Shaw was sent to investigate and on August 22nd was informed that 30 cases of enteric fever had been notified during the preceding 24 hours, and that a very large number of other potential victims were under observation. The patients were scattered throughout the three towns without distinction of age sex occupation or social status. Dr Shaw ascertained that the only factor common to all the patients was the consumption of raw milk retailed by one distributor. This distributor acting on Dr Shaw's advice adopted a method of commercial pasteurisation (heating the milk to 160° F) for the whole of his supply and distributed no unpasteurised milk after the morning round on August 22nd. It was correctly anticipated that this would prevent any further infection direct from the milk supply and that therefore no notification of a primary case of enteric fever would be received after the expiration of the incubation period² calculated from August 22nd plus a week or ten days during which a doctor might not be called in. Some of the alleged late cases were in fact relapses in patients who had failed to call in a doctor in the critical illness. So far as is known only four secondary cases occurred. Dr Shaw concluded that the milk had been infective for a period of about 31 days preceding August 22nd. The total number of known cases finally amounted to 718 (618 residents and 200 visitors). The deaths of residents numbered 51.

No source of infection could be discovered amongst the distributors or retailers. At the 37 scattered farms from which the milk was collected 102 persons were examined and at one farm 2 the wife and son aged 12 of the farmer were found to have enteric fever. Dr Shaw came to the conclusion that neither was the cause of the outbreak but that the milk produced at the farm was the source of infection of the retailer's supply and of the farmer's wife.

In the adjoining house a fatal case of enteric fever

had occurred in May 1934 when the water supply of both houses—common to eight other houses in the vicinity—was suspect. It was derived from a well 162 feet deep situated 100 yards from a small stream which ran within a few yards of the two houses. Repeated examination of the well water proved that it was liable to pollution although at times it yielded a good potable water. At a point about half a mile up stream from the farm the sewage effluent from a house was found to be discharging into the stream. Bacteriological examination of the effluent proved negative for *B. typhosus* in September and early October (4 tests) but the organism was present in large numbers late in October (2 tests). An occupant of the house during the material periods was found to be excreting typhoid bacilli in his faeces; he complied at once with the suggestions made to eliminate any further contamination of the stream.

Dr Shaw was satisfied that the outbreak was due to the consumption of raw milk contributions to the supply having been infected by the contaminated water of the stream. How the infection was conveyed from the stream to the milk whether by the use of the water of a certain well or by the cows subsequent to their drinking at the stream was not determined. The suggestion that a cow may excrete typhoid organisms in her dung or even in her milk is apparently a novel one which Dr Shaw found himself unable to reject.

Sir Arthur MacNalty from the results of the inquiry draws the inevitable conclusion that in the present state of our knowledge where large milk supplies and commensurate risk are involved the only practicable way to reduce the risk of such outbreaks to a minimum is by pasteurisation.

IRELAND

(FROM OUR OWN CORRESPONDENT)

THE NATIONAL HOSPITALS ASSOCIATION
A SET BACK

A LITTLE over twelve months ago a movement was begun to form an Association of Hospitals in Ireland on lines similar to the associations which exist in Great Britain the United States of America and other countries. Its functions were to be consultative advisory and educative. Some fifty hospital authorities expressed interest in the proposal. They included the governing bodies of nearly all the voluntary hospitals and a large proportion of the local authorities which have the control of hospitals. A preliminary meeting of representatives was held just a year ago and a provisional committee was appointed to draft a constitution. This task had been carried out and a meeting was about to be called to consider the draft scheme when it was discovered that the local authorities controlling the rate supported hospitals had no power to contribute toward the expenses of such an association. A deputation waited on the Minister for Local Government and Public Health who explained that he had no power to sanction any such payment by the local authorities. An appeal has been made to him that he should at the earliest opportunity introduce legislation to legalise such payment. As a dissolution of the Dáil is to take place within the next few weeks immediate legislation cannot be expected and the provisional committee of the Association has had no option but to advise that consideration of the

¹ Report on an Outbreak of Enteric Fever in the County Borough of Bournemouth and in the Boroughs of Poole and Christchurch. By Dr Vernon Shaw O.B.E. 31 D. 1 p. pubd. H.M.S. and sold. Lond. No. 81 1937. London. H.M. Stationery Office. 1p. 2s. 6d.

² For purposes of this inquiry an incubation period of 11 days was assumed. Dr Shaw observes that most authorities put it at 12-14 days, that it probably varies with the dose of the infecting organisms, but that it rarely lies outside 7-17 days.

draft constitution be postponed until legislation has been carried. The voluntary hospitals could not, by themselves, bear the financial burden of a hospitals association, and the project cannot be pursued unless the local authorities are given power to join. It is pointed out that the first public suggestion for the formation of a hospitals association came from the Hospitals Commission, the body appointed by the Minister to advise him how best to apply sweepstake funds to the development of the hospital system of the Irish Free State. In the report of the Commission published early last year, comment having been made on the lack of, and need for, coöperation between the hospitals, the formation of a hospitals association was advised. It is further pointed out that there are many precedents for permitting local authorities to pay the expenses of delegates sent to various congresses and conferences—health and engineering, for example, and that one important organisation in Ireland—the General Council of County Councils—is supported by the subscriptions of the several county councils as members. Have the payments in these cases been irregular? If so,

it is high time they were regularised, and such developments as a hospitals association made possible.

THE TWENTY FIRST HOSPITAL SWEEPSTAKE

The draw of the twenty first of the Irish Hospital Sweepstakes was held last week. As a rule the receipts for the sweepstakes on the Derby are smaller than those for the two other sweepstakes of the year, because the period of preparation is briefer. On this occasion, to the surprise of everyone, the receipts showed a slight advance on those for the Grand National, the draw for which was only two months before. In opening the draw Lord Powerscourt, chairman of the Associated Hospitals Committee, was able to announce that the total proceeds to the hospital funds up to the present amounted to £11,118,850. Three county hospitals, eight district hospitals, and three fever hospitals had already been completed out of these funds, and nineteen other hospitals were in course of construction. He had recently received from the Minister a most encouraging and satisfactory assurance as to the prospects of his scheme of hospitalisation.

MEDICAL NEWS

University of Cambridge

On May 28th the following degrees were conferred

M.D.—J. B. Harman
M.B., B.Chir.—J. W. Crofton, J. W. Hannay, T. E. S. Lloyd, W. J. E. Phillips, and G. F. Wright
M.B.—*F. R. Berridge, K. O. Black, F. G. Booker, *F. Braithwaite, T. C. Gipson, A. C. L. Hoult, A. R. Kelsall, C. R. McLaughlin, L. J. Panting, T. L. H. Shore, R. H. A. Swain, W. F. Walton, and J. Woodrow
B.Chir.—*T. M. Daniel

*By proxy

University of Oxford

In future any student who has successfully completed the first three years of a medical course at any university approved by the hebdomadal council may be admitted to the status and privileges of a senior student of the University of Oxford.

It is hoped to make an election at the end of this term to a William Hulme lectureship in physiology at Brasenose College, which will have an initial stipend of £350 a year. It will be tenable for three years and may be renewed for a further two years. Applications should be sent to the principal of Brasenose College before June 26th.

University of Glasgow

On Wednesday, June 9th, at 4.15 p.m., Prof. Ferdinand Sauerbruch, director of the University Surgical Clinic at Berlin, will deliver the fourth Macewen memorial lecture at the university. He will speak on advances in modern surgery and there will be a demonstration by cinematograph on the artificial hand which can be moved at will.

Society of Apothecaries of London

At recent examinations the following candidates were successful:

Surgery—J. R. Audy, Guy's Hosp., A. W. Box, Univ. of Camb. and Guy's Hosp., J. W. P. Morgan, St. Mary's Hosp. and W. G. Zorab, Guy's Hosp.
Medicine—A. Bagon, Univ. of Manch., P. A. Gardner, Guy's Hosp., F. de C. Kite, Univ. of Glasg., B. A. R. Pitt, Guy's Hosp., and R. H. S. Thompson, Univ. of Oxford and Guy's Hosp.
Forensic Medicine—A. Bagon, Univ. of Manch., P. A. Gardner, Guy's Hosp., F. de C. Kite, Univ. of Glasg., B. A. R. Pitt, Guy's Hosp., and R. H. S. Thompson, Univ. of Oxford and Guy's Hosp.
Midwifery—I. Bastawros, Royal Colleges, Edin., A. W. Box, Univ. of Camb. and Guy's Hosp., J. D. B. Perkins, Guy's Hosp., G. L. Young, Univ. of Camb. and St. Bart's Hosp., and W. E. Young, Univ. of Oxford and Guy's Hosp.

The following candidates, having completed the final examination, are granted the diploma of the Society entitling them to practise medicine, surgery and midwifery: A. Bagon, P. A. Gardner, B. A. R. Pitt, R. H. S. Thompson, and W. G. Zorab.

University of London

On May 10th the degree of Ph.D. in medical vital statistics (non clinical) was awarded to Ernest Lewis-Fanning.

University of Durham

At a special convocation to be held in connexion with the centenary celebrations of this University on July 1st and 2nd the hon. degree of D.C.L. will be conferred on Sir Cuthbert Wallace, president of the Royal College of Surgeons of England.

British Homœopathic Congress

This meeting will take place at the Langham Hotel, London, W., on June 17th and 18th. Further particulars may be had from the secretary, 69, Elizabeth street, London, S.W.1.

Bedminster Health Centre

The Lord Mayor of Bristol has opened a new health centre at Bedminster which provides all facilities for the supervision of the health of the pre-school and school child and for the expectant and nursing mother. The routine medical inspections of school-children attending 24 neighbouring schools and the maternity and child welfare services for South Bristol and Knowle will be concentrated here.

Silicosis Symposium

The third Silicosis Symposium will be held at the Saranac Laboratory, Saranac Lake, N.Y., in connexion with the Trudeau School of Tuberculosis, from June 21st to 25th. The meeting will be opened by Dr. Leroy Gardner, director of the laboratory, and at the first session Dr. A. J. Lanza will read a paper on the significance of the silicotic problem and Dr. R. R. Sayers one on the aetiology of silicosis. Prof. Philip Drinker will also open a discussion on dust concentrations and their measurement. On the second day Dr. Gardner will give the opening address in a discussion on the pathology of the pneumoconoses, while Prof. W. S. McCann will speak on the physiology of the fibrotic lung. On June 23rd Dr. E. P. Fendergrass will discuss roentgenologic aspects of the normal and silicotic lung and Dr. H. L. Sampson the roentgenologic diagnosis of silicosis. On June 24th Dr. A. R. Riddell will read a paper on the clinical picture and diagnosis of silicosis with consideration of disability, and Mr. D. E. Cummings on the occupational history. Dr. Riddell and Prof. Drinker will afterwards discuss the control of the disease from the medical and engineering aspects. At the last session Mr. Cummings will consider the administrative aspects of silicosis and Mr. T. L. Water legislative control and compensation.

National Hospital for Diseases of the Heart

On Thursday June 10th at 5 P.M. at 1 Wimpole street London, W. Dr C. Laury, professor of cardiology in the University of Paris will deliver the St. Cyres lecture of this hospital. His title will be *Considérations Pathologiques et Cliniques sur les Rythmes de Galop*

British Social Hygiene Council

Prof James Young director of the department of obstetrics and gynaecology at the British Postgraduate Medical School has been elected chairman of the medical advisory board of the Council in succession to Sir Farquhar Buzzard

Research Defence Society

At a meeting of this society to be held at the London School of Hygiene Reppel street London, W.C. at 3 P.M. on Tuesday June 15th Prof Grey Turner will deliver the eleventh Stephen Paget memorial lecture. He will speak on what research owes to the Paget tradition

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday and cannot appear if it reaches us later than the first post on Wednesday morning

NOTES, COMMENTS, AND ABSTRACTS

REFUGEES AT AN ENGLISH PORT

As medical officer of health for Southampton, Dr H C Maurice Williams sends us a lively account of the arrival there on May 22nd of the Spanish liner *Itabana* with 4058 refugees from Bilbao. At 5 P.M. on the Saturday the ship was signalled off the Needles, and the port sanitary staff accompanied by customs and immigration officials left the docks in the port sanitary launch to board her as arranged. Another launch followed with supplies of milk glucose meat extracts and medical requisites.

It was an extraordinary spectacle. Dr Williams writes to see a vessel normally capable of carrying between 400 and 500 passengers, steaming up Southampton Water with every inch of her decks covered with human beings. Even more extraordinary were the conditions found on board. Children all herded together in the public rooms, in the alleyways and on all the decks. Some were lying rolled in blankets, others running about the ship screaming and a few cool and complacent appeared to accept the circumstances of their arrival in a strange land having been parted from their parents, without any emotion. It was with some difficulty that we were able to reach the ship's hospital to see a boy of 12 who, later the same evening was removed by launch and ambulance to the borough hospital for an operation on a strangulated testicle.

The ship was permitted to proceed to an inner mooring station next morning for a detailed medical inspection of all persons on board. On the Sunday morning hundreds of the public with press representatives and photographers had collected along the quay but no one without an official pass issued by the port sanitary department was permitted to approach the ship's berth or go on board. The names and addresses of all who were given these official passes were recorded in order that the health authorities throughout the country might keep them under a surveillance in the event of any major infection being discovered amongst the persons on board. The adults accompanying the children were first examined. The saloons were then cleared of all except those taking part in the medical and immigration inspection, and within half an hour the children were lined up in queues and the inspection began.

"Nine medical officers of the department each in a separate screened cubicle took up their positions in the line of the queue. A health visitor assisted each doctor by stripping the children to the waist. The child was then examined, special attention being paid to an examination of the eyes for trachoma, the head for ringworm lice or nits, and the skin for rashes and lice. The heart and lungs were also examined in detail to decide on those fit to live under canvas.

"On completion of the examination each child was dressed by a health visitor and passed on in the queue to a sanitary inspector who stamped the identification card attached to each child indicating that the child had been medically examined. In addition he also tied a coloured tape on the child's left wrist which served as a code as to the destination of the child. White tape indicated clean and allowed the child to proceed direct to camp. Red tape indicated verminous and to proceed to the corporation bath for de-lousing. Blue for infectious or contagious conditions to proceed to the isolation hospital or other institution. Blue and white tapes for any other condition requiring general hospital treatment.

After the medical inspection was completed each child was passed on to the immigration officer who stamped the disc with his official stamp and the child then proceeded down the main gangway at the foot of which sanitary inspectors and health visitors collected them into groups according to the colour of the tapes and arranged for their immediate disposal in the following ways: Clean children went direct by motor omnibuses to the camp. Verminous children were taken in lorries to the corporation bath for de-lousing and the hospital cases were transported by the corporation ambulances to the appropriate institutions.

Many of the children were thin but the general impression gained especially before they stripped was that they were for the most part, an alert, intelligent group of children who compared favourably in physique with our own children. The clothing generally was very good and when the clothing of the verminous ones was taken away from them for disinfection many of them wept.

At the corporation baths we were allowed to use 40 of the slipper baths, and with the assistance of many voluntary and willing helpers together with twelve barbers 712 of the children were de-loused and fitted with complete sets of clothing the latter being supplied by the Spanish Relief Committee.

At 7 P.M. on the Sunday medical inspection ceased for the day. The medical staff had worked continuously for ten hours and had disposed of 9278 children. On the following morning the remainder were examined and completed by 11 A.M.

DR RIADORE AND THE EFFECTS OF SPINAL IRRITATION

Mr D O Thomson, writing from the registered office of Osteopathic Trusts Ltd complains that in the opening sentence of an annotation entitled

What is Osteopathy? in our issue of April 10th we pled its American origin to discredit this theory of healing. He goes on to say: although Still began to elaborate on his initial heresy at the end of the nineteenth century a British doctor preceded him in a tentative announcement of similar conclusions. Many years earlier namely in 1842 was published in England an interesting suggestive treatise on Irritation of the Spinal Nerves as the source of Nervousness Indigestion Functional and Organical Derangements of the Principal Organs of the Body by J Evans Riadore, M.D. and of the Royal College of Surgeons London. In this book the author discusses a lengthened catalogue of maladies which are either engendered by continued by or the consequence of either spinal irritation or inflammation, with or without curvatures of the spinal column—a class of disease of no small importance, whether we regard their frequency or the suffering and danger which attend them the nature of which in consequence of our erroneous views of the animal economy has been overlooked, and the sufferer thus deprived of all chance of effectual assistance from our art.

Dr Riadore's name appears in the London Medical Directory for 1846 with the qualifications M.D. Glissen and M.R.C.S. (April 4th 1817) and an address at 73, Harley-street.

NEW PREPARATIONS

EXAMIN—What is described as the purest and most highly concentrated liver extract ever achieved on a manufacturing scale has been put on the market by Glaxo Laboratories Ltd Greenford Middlesex. On Jan. 10th last in our correspondence columns, Laland and Klem of Oslo described this product and mentioned that it would be made available shortly. Each 2 c.cm ampoule is said to contain in an average of 10–15 mg. of solids the haemopoietic factor extracted from 100 g. of fresh liver. The initial dose in relapse is given as 4 c.cm by injection and the maintenance dose at fortnightly intervals as 2 c.cm. It is claimed that Examin does not cause pain after injection and does not give rise to allergic reactions. It can be administered intravenously in emergency.

NAVIGAN—Last year we published reports on the use of Syntropan with Sedormid as a preventive and remedy for sea-sickness (*Lancet* 1936 i 220, 1213). Syntropan (a diethylaminodimethylpropyl ester of tropic acid) is a synthetic antispasmodic substance related to atropine which depresses the action of the vagus, and especially its action on the

digestive tract. Sedormid, the sedative experimentally associated with it, has now been replaced by a pyridine derivative chemically known as dihydroxy-diethylpiperidine, which is described as a mild sedative-hypnotic having pharmacological properties resembling those of carbomalum B.P. The manufacturers, Roche Products Ltd (51, Bowes road, London, N 13), call their new syntropan preparation Navigan and recommend it both for the prevention of travel-sickness (air, sea, train, car) and, more tentatively, as an antispasmodic in abdominal colic. Navigan is given by mouth in small tablets, or, if need be, in suppository form. Accounts of its use at sea have been encouraging.

"WELLCOME" BRAND WHOOPING COUGH VACCINE
In issuing their vaccine made from recent strains of *Haemophilus pertussis* (Bordet-Gengou bacillus) Burroughs Wellcome and Co point out that there is no satisfactory laboratory test for potency and that batches of vaccine made in different parts of the world may not all be effective in preventing whooping-cough. In the attempt to secure immunity against this serious disease inoculation in infancy is advised, preferably between the 7th and 10th months. Kendrick and Elderling's technique comprises five subcutaneous injections (at weekly intervals) with a total of 70,000 million organisms. Madsen gives less and Sauer more. The reactions seem to be somewhat more troublesome than those of anti diphtheria immunisation, especially in older children. If the vaccine is used for treatment—on which opinions differ—it should be used early. It is prepared at the Wellcome Physiological Research Laboratories, Beckenham, Kent.

FOLINERIN is a crystalline glucoside obtained from the leaves of the oleander shrub (*Nerium oleander*) and marketed by Schering Ltd, 185, High Holborn, W O 1. It is intended for administration, by mouth, in cases where digitalis would normally be given but a more rapid and constant action is desirable. It is said to be a more powerful diuretic than digitalis and to have a more persistent action on the heart. Stability towards acids prevents its decomposition in the stomach, and as a rule it causes no nausea.

KINOO PURE SILK BABY POWDER—The manufacturers, Kinu Ltd (6, Finsbury-square, E C 3), state that every tin of their Kinoo Baby Powder contains at least 90 per cent of pure cocoon silk, with about 5 per cent of boric acid and 5 per cent of zinc oxide. The powder is soft and silky to the touch as might be expected from its origin, and it is said to be free from the disadvantages sometimes attached to talc, chalk, starch, kaolin, and other substances often applied to the skin. Among its virtues are "great absorbency without the possibility of fermentation, dissolution, or the formation of a smeary paste."

ZEPHIRAN CONCENTRATE is a new antiseptic made by Bayer Products Ltd (Africa House, Kingsway, W C 2). It is described as a watery solution of a mixture of alkyl dimethylbenzylammonium chlorides, forming a faintly perfumed colourless fluid which does not stain clothes or dressings. Subcutaneous and intracutaneous injections of a 1 in 100 dilution into the ear and abdominal skin of a rabbit are stated to cause no irritation of the tissues, and rabbits tolerate 3-5 c cm per kg of body-weight, taken by mouth. Tests at a London teaching hospital have shown a Rideal-Walker coefficient (*Bacillus typhosus*) of 75, but the action of the disinfectant for certain other organisms is relatively greater, and comparable figures for haemolytic streptococci *Staphylococcus aureus*, and pneumococci are given as 27, 31, and 137 respectively. In concentrations up to 1 in 500 Zephiran Concentrate makes a strong lather and no soap need be employed when it is used for disinfection of the hands. When it is employed for sterilising instruments anti rust tablets should be added, and these are supplied free on demand. The manufacturers claim that even when

it is diluted with equal parts of serum their antiseptic retains very considerable bactericidal power.

Wishing to show that BISODOL is more than a crude mixture of its component parts, the makers (Bisodol Ltd, 12, Chenies street, W C 1) invited us to see its manufacture. The ingredients are sodium bicarbonate, light magnesium carbonate, and bismuth subnitrate, with the ferments diastase and pepsin, and special attention is paid to their subdivision in the powder, for on this depends the uniformity of the suspension formed when water is added. After a preliminary mixing the powder materials are passed through a fine-mesh silk screen into a mixing chamber, where they are stirred with revolving blades for two hours. Peppermint oil is here added in a fine spray from an atomiser.

BISMUTH THERAPY. CORRIGENDUM.—In a note published on May 22nd reviewing a booklet issued by Pharmaceutical Specialities (May and Baker) Ltd., reference is made to a technique for intravenous injection of bismuth. Actually the technique described was for intramuscular injection, its object being to ensure that the needle is *not* in a vein, and the manufacturers did not suggest that bismuth can be given by the intravenous route.

MENTAL HYGIENE CONGRESSES IN PARIS—The second International Congress on Mental Hygiene will be held in Paris from July 19th to 24th under the presidency of Dr Edouard Toulouse. The congress will meet at the Centre Marcelin Berthelot, Maison de la Chimie, 28 bis, rue Saint Dominique, Paris, VII. Copies of the final programme of the meeting may be had from the secretary of the National Council for Mental Hygiene, 76, Chandos House, Palmer street, London SW 1.

From July 24th to August 1st the first International Congress of Child Psychiatry will meet at the same place. The inaugural address will be given by Prof H Wallon, who will speak on the neurophysiological principles of child psychiatry. Other subjects which will be discussed are conditioned reflexes in child psychiatry, methods of education according to disturbances of intelligence and character in children and mental debility as a cause of delinquency in children and adolescents. Further information may be had from Dr Grumbert, 11 rue Duroc, Paris, VII.

Births, Marriages, and Deaths

BIRTHS

HYATT—On May 21st, at Everecreech Somerset, the wife of Major J W Hyatt R.A.M.C. of a son.
JACKSON—On May 23rd at Devonshire place W, the wife of Mr Harvey Jackson F.R.C.S. of a son.
PANTIN—On May 25th at Bentinck street W the wife of Dr Guy Pantin of a daughter.

MARRIAGES

GOADBY—BOGGON—On May 22nd at Winchester Cathedral Hector Kenneth Goadby M.D., F.R.C.P. only son of Sir Kenneth Goadby K.B.E. and Lady Goadby to Margaret Evelyn daughter of Mr R O Boggon O.B.E. of Worthing formerly of H.M. Dockyard, Portsmouth.

DEATHS

COLLINS—On May 24th at Manor Park E Richard Hawtrey Collins, M.D. Brux., M.R.C.S. Eng. aged 74.
HCOILL—On May 28th at Streatham Park S.W., George Frederick Hugill M.D. Durh.
KEMPER—On May 20th at Edinburgh Arthur Thomas Kemper, F.R.C.S. Edin. for many years medical missionary at the O.M.S. Hospital Hang-chow China.
LANGTON—On May 27th following an operation in Kampala Edward Athol Clarence Langton M.R.C.S. Eng. Uganda Medical Service aged 48.
LEE—On May 26th in London William Emerson Lee M.D. Camb. of The East Sussex Club St. Leonard-on-Sea, aged 61.
PAULSON—On May 20th at Heybrook Bay near Plymouth, William Paulson L.R.C.P. Lond. late of Mountsorrel Leicestershire and Dartmouth in his 95th year.
SHORNEY WEBB—On June 1st, at the Middlesex Hospital C H Shorney Webb M.S. F.R.C.S.
WALLER—On May 20th at Stroud Glos Alfred Whalley Waller M.D. Durh. M.R.C.S. Eng.

A fee of 7s 6d is charged for the insertion of Notices of Births, Marriages and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

SIMPLE NON SPHINCTERIC SPASM OF THE OESOPHAGUS

Br JOHN E G MCGIBBON, M.B. B.S. Lond. D.L.O.
HOY LARYNGOLOGIST TO THE ROYAL SOUTHERN HOSPITAL,
LIVERPOOL AND

J H MATHER, M.B. B.Sc. Liverp. D.M.R.E.
HOY RADIOLOGIST TO THE HOSPITAL

SPASM is the most common individual manifestation of oesophageal disease, and in the gullet its significance as an entity is probably greater than in any other tubular organ of the human body. In fact as Barclay (1931) has stated when discussing the radiology of the oesophagus spasm may be responsible for the whole of the symptomatic disturbance presented by any intrinsic or extrinsic lesion.

It may be the sole radiological abnormality observed in such varying pathological states as intra-oesophageal injury, impaction of small non-opaque foreign bodies, oesophagitis, central and peripheral nervous lesions, and it may mask completely an early oesophageal malignancy. Teschendorf (1928) has described such a case in which a carcinoma of the oesophagus became obvious by radiological examination only after the accompanying spasm had been dissipated by an injection of atropine.

CLASSIFICATION

Anatomically spasm that develops at either the upper or lower (sphincteric) extremity of the oesophagus can be regarded as distinct from that arising in the intervening (non-sphincteric) part although their pathology probably is similar. Non-sphincteric spasm may be present in an apparently healthy oesophagus, or it may accompany a true intrinsic lesion. In the earlier articles the former was designated a primary functional or "idiopathic" spasm and the latter a secondary spasm. Consideration of the aetiology of non-sphincteric spasm of the healthy oesophagus shows that a so-called primary spasm is usually due to an altered state or disease of some other organ of the body and the term simple non-sphincteric spasm will be used to describe this lesion in the following notes.

Abel (1929) has classified spasm of the non-sphincteric portion of the oesophagus on an aetiological basis as follows—

- (1) Psychological oesophagismus.
- (2) Reflex oesophagismus—i.e. spasm secondary to disease of other organs.
- (3) Symptomatic oesophagismus—i.e. spasm due to (a) disease of the oesophagus itself; (b) organic disease of the central or peripheral nervous system; or (c) toxic lesions.

All of the above except spasm due to oesophageal disease (3a) and some toxic cases (3c) can be included under the title of simple non-sphincteric spasm.

EXTENT AND TYPES

Simple non-sphincteric spasm may affect one or more segments of the oesophagus, its entire extent or a varying portion of its length and according to the radiological appearances observed the following types may be described and are shown diagrammatically in Fig. 1—

- 1 Localised spasm (Fig. 1 B)

5937

2. Diffuse spasm:
 - (a) tetanic: (1) total (Fig. 1 C) (2) partial (Fig. 1 D)
 - (b) irregular (Fig. 1 E)
 - (c) functional diverticula (Fig. 1 F)

Each type may vary considerably in the same and different patients, and occasionally the various types may occur in the same individual.

Localised spasm is probably the most common type. It affects only a small annular segment or segments of the oesophagus (Fig. 7) and when more than two segments are contracted simultaneously

FIG. 1.—A. Normal oesophagus. B. Localised spasm. C. Total tetanic spasm. D. Partial tetanic spasm. E. Diffuse irregular spasm. F. Functional diverticula.

it is advisable to regard the lesion as a type of diffuse spasm. It may be present in any portion of the oesophagus and Reyner (1924) has stated that its site may vary in the same patient.

Diffuse spasm was recorded under this title by Moersch and Camp (1934) and should include the so-called functional diverticula described by Barsony and Polgar (1927) and by Gregoire (1926). The tetanic form of diffuse spasm may involve the entire extent of the gullet so that opaque food cannot enter its lumen and on radiological appearance obstruction at the inlet only may be diagnosed or it may be confined to the lower half or third of the viscous. Irregular spasm arises in that portion of the oesophagus controlled by unstriated muscle and it appears to be an exaggeration of its normal peristaltic contractions. Kohler (1928) holds that it is very difficult, indeed almost impossible to observe peristalsis in a normal oesophagus or even above an organic stricture so that the radiological appearance of this type of spasm are very striking and are well shown in Fig. 4. Functional diverticula (Fig. 8) become manifest only at the height of muscular contraction and they are due to the development of spasticity of two or more segments separated by atonic areas. The radiological appearances vary from that of a simple arching of a small portion of the oesophageal outline to a mushroom or hat-shaped diverticulum. Gregoire (1926) has described the diverticula as pear-shaped dilatations which overhang the succeeding contracted segments. Often they are multiple—Barsony and Polgar (1927) report 5 cases out of 9 which were multiple—they arise at any level of the oesophagus and they are associated sometimes with atony of the entire organ or with localised spasm. A functional diverticulum may be the starting point of a true organic pulsion diverticulum, and the writers mentioned above observed such a development in one patient.

DURATION

As a rule all types of spasm are *transient*—there is only a tendency to spastic contraction of the oesophageal muscles, and when this does occur it is of short duration. Occasionally transient spasm is observed accidentally, this happened in Case 5 below, and it is probable that it is more common than is generally believed, but that it escapes recognition owing to its short duration and the absence of symptoms. Less often spasm is *intermittent* as in Cases 4 and 8 below—for example, spasm may occur after some special dietary, thermic or psychical stimulus. Very rarely spasm is *persistent* owing to the continuance of the exciting cause, or possibly to the development of a nerve-cell habit as described by Chevalier Jackson (1934). Thus in Case 2 spasm lasted for 3½ years, and in Case 1 for 7 weeks. Moersch and Camp (1934) have recorded notes of a patient in whom spasm was present for 9 years, and Barclay (1931) quotes Grier's account of a man with complete obstruction of the middle third of the oesophagus due to spasm which persisted for 2 months.

NERVE SUPPLY OF THE OESOPHAGUS

The type of spasm under discussion is a neurogenic manifestation, and it is necessary to consider briefly the nerve supply of the oesophagus. This is derived from the vagi and from the sympathetic chains and is shown diagrammatically in Fig 2. The vagal supply has been recognised for a long time and it is now definitely established that there is also a contribution from the sympathetic system. There are known branches from the inferior cervical ganglia and from the coeliac plexus, which accompany the left gastric artery, but the question of the existence of direct branches from the thoracic sympathetic ganglia is still controversial.

Kuntz (1929) is of the opinion that the sympathetic supply for the oesophagus comes chiefly from the

FIG 2.—Diagram of the nerve supply of the oesophagus.

inferior cervical ganglia but that further branches do pass directly from the thoracic ganglia, or from these ganglia via the aortic plexus or a plexus in the posterior mediastinum to the gullet. Other writers

FIG 3.—A, Normal oesophagus. B, Stimulation of vagi or removal of stellate ganglia. C, Stimulation of sympathetic or division of vagi.

Effect of Nervous Impulses

Region of oesophagus	Stimulation of vagus alone	Bilateral removal of stellate ganglia	Stimulation of stellate ganglia	Bilateral division of vagi
Upper third	Tetanic contraction which only persisted with constant stimulation. No secondary waves.	Hyper-tonicity.	Nil.	
Middle third	Tetanic contraction followed by secondary waves.		Diminution of tone or increased contraction.	Dilatation with recurring peristalsis in the lower third.
Lower third	Increased tone and mobility which persisted or continued as a series of secondary waves.	Increased peristalsis. Sphincter normal.	Slight diminution of tone and mobility.	Contraction of sphincter.

doubt the existence of a thoracic sympathetic supply. The following short description is quoted from an article by Woollard (1935) —

"Slender sympathetic filaments from the inferior cervical and thoracic sympathetic ganglia travel alongside the intercostal vessels, but they are too small and delicate to trace beyond the front of the vertebral column and the aorta. It seems unlikely that the oesophagus receives other than a very scanty sympathetic supply from the adjacent ganglia. Sympathetic fibres, however, do reach the oesophagus from above, having entered the vagi from the cervical sympathetic chain. The other route by which sympathetic fibres may reach the cardia is by way of the coeliac plexus from which they may travel in company with the left gastric artery."

As a result of the findings of Cannon (1907), Meltzer (1898), and other investigators it is now generally agreed that vagal stimulation causes increased tone and mobility of the plain muscle portion of the oesophagus (Fig 3 B) and that sympathetic stimulation inhibits this (Fig 3 C). The experimental work of Knight (1935) has done much to explain the varying and often apparently contradictory results obtained by previous workers, for he has shown that the type of reaction obtained by stimulation of the extrinsic nerves of the oesophagus depends upon the nature—whether striated.

or unstrated—of the muscle content of the region under consideration. In Knight's experiments cats were used as their oesophagus approach most nearly to man in regard to distribution of striped and unstriped muscle and his conclusions are given in the Table and shown diagrammatically in Fig 3.

From a consideration of this it appears that spasm of the oesophagus might be caused by an abnormal increase of stimuli travelling via the vagi by a decrease or cessation of impulses via the sympathetic, or by an imbalance of the two sets of impulses. The origin of such excitatory or inhibitory impulses is still undetermined but the findings of Carlson Boyd and Pearcy (1922) who showed that stimulation of the gall bladder intestines and urinary bladder gave rise to oesophageal activity is suggestive and Alvarez (1928) has stated that inhibitions that are produced by fear, worry or illness probably travel by way of the sympathetic.

INCIDENCE

Simple non sphincteric spasm is not commonly diagnosed as probably in many cases the condition is of very short duration and its symptoms evanescent. Negus (1936) has stated that he has never observed a true example of simple spasm and that although he has examined patients who had been diagnosed as suffering from such by radiologists and physicians they ultimately proved to have an organic oesophageal lesion. Guibez (1923) is of the opinion that simple spasm of the non sphincteric portion of the oesophagus, except in its upper third, is never seen. Chevallier Jackson (1934) also questions its occurrence and Baldenweck (1925) regards these cases as rare and ephemeral, presenting only in neurotic females and alcoholics. These authoritative statements cannot be disregarded. On the other hand Moersch and Camp (1934) have reported a series of 8 patients with simple diffuse spasm. Tenchendorf (1928) and Barsony and Polgar (1929) all have recorded notes of large series of cases, and Sudhues (1932) has called attention to the presence of simple spasm in children. Brown Kelly (1936) considers that this type of obstruction in the oesophagus is quite common and the present series consists of 8 cases seen in the past five years 4 of which were described briefly during a recent discussion at the Royal Society of Medicine.

ETIOLOGY

This type of spasm may occur at any age. In our series the youngest patient was aged 8 months and the oldest was 70 and it affects both sexes equally. Many theories on the cause of simple non sphincteric spasm have been advanced.

Congenital inferiority of the sympathetic nervous system in children has been suggested by Sudhues (1932) and Brown Kelly (1936) is of the opinion that in such young patients there may be a congenital predisposition to spasm which occurs only when the child is ailing or thwarted.

Nervous instability as a cause is mentioned by a large number of observers. Patients who suffer from simple spasm are usually highly strung and nervous, and the attacks may be precipitated by nervous

FIG 4 (Case 1)—Simple diffuse irregular spasm of the lower half of the oesophagus probably due to a phobia. This should be compared with Fig 14 in Knight's (1935) article which depicts a radiogram of a cat's oesophagus after bilateral removal of the stellate ganglia.

FIG 5 (Case 2)—Localised spasm of lower oesophagus of 31 years duration, probably due to a phobia. Radiogram shows a smooth stricture with "awl-shaped" end.

excitement, worry, anger or grief. Lust (1923) has recorded the occurrence of simple oesophageal spasm in children when presented with food which was distasteful to them. Moersch and Camp (1934) consider that nervous instability is more evident in these cases than it is in patients who suffer from achalasia. Spasm due to emotional disturbances corresponds to Abt's (1920) psychological oesophagismus and he has mentioned the theory of Lemaître that a small superficial abrasion of the oesophageal mucous membrane that would pass unnoticed in a normal person may give rise to spasm in an unduly receptive individual. Bruzzi and Alagna (1930) also consider such slight trauma to be a common causal factor.

Two cases of simple non sphincteric spasm apparently due entirely to a phobia were present in our series—

CASE 1—A female aged 35 stated that 7 weeks previously she thought a crust stuck in her throat and

since that date she had experienced difficulty and pain on swallowing. General clinical examination was negative. Radiography showed a diffuse irregular outline of the lower half of the oesophagus (Fig 4). Endoscopy revealed no lesion of the oesophagus, and the symptoms and abnormal radiological appearances disappeared after passage of the oesophagoscope.

It is interesting to note the similarity of the radiological appearances of this patient's oesophagus and that of Fig 124 in Knight's (1935) article which

only produced by deglutition and *not* by stimulation of the pharynx alone. In his opinion this type of spasm usually occurs in nervous females aged 18-30, and never below the upper third of the oesophagus. This subdivision should not include those cases in which a large, ill masticated and hurriedly swallowed bolus gives rise to a brief oesophageal spasm, as this is not a disorder of deglutition, but rather that the mass has acted as a temporarily impacted foreign body.

FIG 6 (Case 5) — Simple localised spasm of oesophagus observed accidentally in a patient with chronic gastric disease

FIG 7 (Case 7) — Simple localised spasm of oesophagus of 2 days duration and unknown aetiology. The radiogram shows a smooth rounded outline of the stricture with atony of the upper portion of the oesophagus

depicts a cat's oesophagus after bilateral removal of the stellate ganglia.

CASE 2 — A female aged 53 stated that she had experienced pain and difficulty in swallowing for 3 months so that she could take only soft food, and that she thought she was "suffering from cancer." General clinical examination was negative. Radiography showed "definite spasm present at lower part of gullet." The blood Wassermann reaction was negative. Oesophagoscopy revealed a stricture with some associated oesophagitis of the lower third of the oesophagus (Fig 5). This was dilated without improvement in swallowing, and two years later as the lesion was considered to be neoplastic a Souttar's tube was inserted into the stricture and left in situ for a year. Six months after removal of the tube the dysphagia disappeared and radiography showed that the paste made a normal passage to the stomach. The patient has remained well for nine months.

Disorders of deglutition are suggested as a cause of spasm by Guisez (1923). He has stated that spasm "primitif" is nearly always due to trouble in the act of swallowing, since oesophageal peristalsis is

nervous lesion occurred in the present series —

CASE 3 — A male aged 8 months, suffering from primary amentia, was admitted to hospital with a history of attacks of screaming on and off for four months and regurgitation of feeds during the preceding two days. General clinical examination was negative. Radiography showed a complete hold up of the test paste in the oesophagus at the level of the 6th dorsal vertebra. Oesophagoscopy revealed no abnormality of the oesophagus save that the mucous membrane was redder than normal. The child died in spite of feeding by means of a stomach tube. Permission for an autopsy was not obtained.

Reflex stimulation from lesions of the thoracic and abdominal viscera has been regarded as a cause of simple non sphincteric spasm by numerous observers. The experimental results of Carlson and his co-workers (1922) have been mentioned above. Moersch and Camp (1934) record notes of a man who suffered from simple spasm for nine years, he was found to be suffering from a duodenal ulcer and the spasm was cured by performance of gastro enterostomy. Teschendorf (1925)

Organic disease of the central or peripheral nervous system is a probable cause of oesophageal spasm. It may occur in nervous disorders such as tabes, bulbar palsy, exophthalmic goitre, and in organic or toxic lesions of the oesophageal nerves. Mosher (1933, 1934) has shown that in acute and chronic general or abdominal infections and also in general degenerative conditions lymphatic permeation and fibrosis may occur in the lower part of the oesophagus, and Rake (1930) and other observers have demonstrated atrophy of the oesophageal nerve ganglia in cases of achalasia. Simple non sphincteric spasm associated with achalasia has been reported by Forbes (1926) and Teschendorf (1928), and Barsony and Polgar (1927) have watched the incidence of mega oesophagus in patients who previously exhibited functional diverticula. It is not difficult from the findings of the above observers to formulate a theory that the vagal nerve-endings may be irritated by toxic or degenerative products giving rise to spasm, they then recover or atrophic changes supervene leading to achalasia and mega oesophagus. One case of simple non sphincteric spasm due to an organic central

recounts the findings of several writers who have seen simple spasm of the oesophagus apparently caused by reflex stimulation from carcinoma of the stomach simple ulcer of the stomach and duodenum disease of the gall bladder movable kidney hernia and lesions of the uterus lung mediastinum and aorta. Three cases of simple non-sphincteric oesophageal spasm associated with gastro intestinal disease occurred in the present series —

CASE 4.—A female aged 45 gave in 1933 a history of four years intermittent difficulty and pain on swallowing. Radiography oesophagoscopy and biopsy showed a peptic ulcer of the oesophagus 13 in. from the incisor teeth. A few weeks later oesophagoscopy was repeated and the ulcer was then found to be healed by scar tissue. Since that date the patient has had attacks of complete oesophageal obstruction lasting two or three days and recurring three or four times a year although repeated oesophagoscopy has been negative in regard to any intrinsic lesion. It has been very difficult to persuade her to come to hospital during an attack of dysphagia. It was possible however to radiograph her during the most recent attack and the film which will not reproduce showed diffuse tetanic spasm of the lower third of the oesophagus. This patient is known to be suffering from a duodenal ulcer and the frequency of the spasmodic attacks has been lessened by the administration of large doses of alkalis.

CASE 5.—A male aged 52 gave a history of four years chronic gastritis and was found to have in addition complete achlorhydria and a microcytic anaemia. Routine radiography showed a simple oesophageal spasm (Fig. 6). Unfortunately the patient was not examined with the oesophagoscope but the subsequent disappearance of his symptoms following treatment and lack of recurrence over a long period is proof of the correctness of the diagnosis.

CASE 6.—A male aged 40 suffering from a duodenal ulcer was admitted to hospital under the care of Mr J. T. Morrison by whose kindness we examined the case. He complained of dysphagia and occasional pain in his left shoulder on and off for 12 months. Radiography showed a narrowing of distal third of oesophagus with dilatation above. Growth involving lower third of oesophagus. By oesophagoscopy no intrinsic lesion was found, but spasm of the lower part of the oesophagus was observed. He has been free from dysphagia since but nearly 5 years later he was readmitted for another complaint and radiograms showed some dilatation of the lower half of the oesophagus without any evidence of obstruction.

Other cases.—There is a residue of cases in which none of the above factors is evident but possibly this may be due to an incomplete clinical examination. The two following patients both exhibited simple spasm of the oesophagus without any other discernible lesion but in view of their ages there are many possibilities —

CASE 7.—A male aged 79 stated that he had been unable to swallow even fluids for two days. He gave a history of two similar attacks of dysphagia—15 years and 10 years previously. A radiogram by Dr P. H. Whitaker showed a complete smooth rounded hold up of food past in the lower third of the oesophagus (Fig. 7). Oesophagoscopy revealed no intrinsic lesion. He swallowed comfortably two days later and a further radiogram demonstrated a normal passage of opaque meal to the stomach.

CASE 8.—A female aged 77 was examined by the courtesy of Mr C. A. Wells. She complained of attacks of substernal pain which were relieved by vomiting mucus on and off for 7 years. She had not lost weight and her general health was good. Five weeks before examination she had vomited blood on four occasions. General clinical examination was negative. Radiography of the oesophagus by Dr Whitaker showed a pouch like appearance in its lower third. This was shown in a series of radio-grams (Fig. 8). A few days later she was admitted to

hospital when X ray examination showed no abnormality of the oesophagus and oesophagoscopy was negative. The patient has continued to suffer from attacks of pain and regurgitation at fortnightly intervals without any symptoms in the intervening periods.

SYMPTOMS AND SIGNS

Simple non sphincteric spasm may give rise to no symptoms whatever and it may be discovered accidentally as in Case 5 above. More commonly intermittent dysphagia and pain on swallowing are outstanding features, and the pain varies in character from a dull substernal ache to severe shooting paroxysms, which occasionally occur spontaneously and awaken the patient at night—in two cases reported by Moersch and Camp (1934) the pain was so severe that a diagnosis of angina had previously been made. In the present series the pain complained of was of the

FIG. 8 (Case 8).—Solitary functional diverticulum of the lower oesophagus.

dull aching variety. These symptoms may be accompanied by a feeling of anxiety and sometimes by palpitation and dyspnoea. Barony and Polgar (1927) state that functional diverticula may occur without symptoms and that patients who do experience pain and dysphagia have in addition some dilatation of the oesophagus. During the acute phase swallowed material is regurgitated and regurgitation is the predominant symptom of spasm in children.

RADIOLOGY

The routine examination of the oesophagus is made with the patient standing in the left posterior oblique position—that is in a semi lateral position with the left shoulder resting against the fluorescent screen—so that a clear space can be seen between the cardiac and aortic shadows anteriorly and that of the vertebral column posteriorly. The head is turned slightly towards the left shoulder and the chin raised to obtain a clear view of the pharynx. The patient is given a spoonful of opaque food of the consistency of very thick cream which is retained in the mouth until directions are given to swallow and the passage of the opaque bolus is then watched through the pharynx and oesophagus into the stomach. If no abnormality is detected the patient is questioned as to the exact character of the food which gives rise to dysphagia and the consistency of the opaque food should be altered or crumbs of toasted bread added and the examination repeated. For as Barclay (1931) has pointed out at one examination the opaque

food allays the irritation and no obstruction is observed, at the next a hard particle may set up the irritation and produce spasm." Radiograms are taken immediately after the screen examination and also with the patient standing in the right posterior oblique and anterior positions, as an abnormality may be demonstrated more clearly in either of the latter positions. When spasm is demonstrated it is advisable to repeat the examination later in the day, on the following day, or even at a still later date.

Many of the radiological features of simple non-sphincteric spasm have been mentioned in the text of this article but the following additional points may be noted—

(1) Spasm is best observed radioscopically because of its changing appearance.

(2) In diffuse and localised spasm the area above the hold up is everywhere smooth.

(3) The shadow of the paste above a localised spasm has usually a rounded end as in Fig 7, or occasionally an "awl-shaped" end as in Fig 5.

(4) With the patient supine and the hips raised it is possible in some cases to fill the portion of the œsophagus below the spasm with opaque material.

(5) Atony of the œsophagus may be associated with spasm. In Fig 7 an enlarged œsophageal shadow is shown which is due to atony and not to pressure dilatation, as the spasm had been present only for two days and the œsophagus showed normal radiological dimensions when the spasm had resolved, whereas Fig 5 shows no enlargement of the œsophageal shadow although the spasm had persisted for 3½ years.

(6) At other times there is a definite increase of tonus of the muscles, particularly in cases of diffuse spasm when the entire œsophageal shadow may appear as a narrow ribbon between the actual attacks.

TREATMENT

In many patients simple non-sphincteric spasm resolves spontaneously, whilst in others it persists in spite of active treatment, and a consideration of the many presumptive causes demonstrates the impossibility of generalisation in regard to treatment and affords an explanation of its failure in numerous cases.

All of the possible causative factors must be sought for in each patient, and if found the appropriate psychological, therapeutic, or surgical corrective measures can be adopted. The success of this approach to treatment is illustrated by the patient of Moersch and Camp (1934), who was cured after nine years suffering by gastro-enterostomy, Case 1 above in whom reassurance brought about resolution of the spasm, and Case 4, who is improving with massive doses of alkalis.

On the other hand a study of the case notes recorded above shows that symptomatic treatment alone is unsatisfactory—for instance the mere passage of an œsophagoscope or even actual dilatation will not bring about relief of spasm as it will do in the sphincteric regions. This fact also has been mentioned by Moersch and Camp (1934) and is illustrated by Case 2 above. As regards drugs, sedatives and antispasmodics do not appear to be of great assistance. Teschendorf (1928) advises large doses of atropine pushed almost to the limit of safety. Apomorphine has been given by Boehm (1921), and Lepameter and Dermas (1926) report resolution of symptoms after the administration of Sedobrol.

SUMMARY

Spasm arising in that portion of the œsophagus between the cricopharyngeus and the cardiac sphincter without any intrinsic œsophageal lesion is described as simple non-sphincteric spasm of the œsophagus.

The diagnosis of this is a dangerous one without the most careful investigation, as spasm of the œsophagus is common and may mask a grave lesion.

Simple non-sphincteric spasm may be localised or diffuse and includes the so-called functional diverticula, and it may be transient, intermittent, or persistent in character.

The radiological appearances are typical, and as a rule œsophagoscopy is negative.

It is a neurogenic manifestation and is often associated with other nervous manifestations such as general atony or increased tonus of the œsophageal muscles. Occasionally it may be followed by achalasia or mega-œsophagus.

This type of spasm appears to be secondary to disease or an altered state of other organs, and if it does not resolve spontaneously satisfactory relief can only be obtained by treating the primary lesion.

In addition to the acknowledgments made in the text our thanks are due to Dr R. Steel and Dr Swanson Hawks for the radiological reports in Cases 2 and 5 respectively, and to Dr T. J. O'Donnell for the after history of Case 8.

URINARY SUPPRESSION FOLLOWING BLOOD TRANSFUSION

WITH REPORT ON A CASE PROBABLY DUE TO OVER HEATING THE BLOOD

By S. L. BAKER, M.Sc. M.Ch., Ph.D. Lond.,
M.R.C.S. Eng.

PROCTER PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF MANCHESTER

DEATH following and attributable to blood transfusion may occur immediately—i.e., within a few minutes or hours—or after an interval of several or many days. The causes of the rapid deaths usually remain doubtful and are difficult to investigate and to separate from the primary condition for which the transfusion was performed.

The delayed deaths are the result of complete or partial suppression of urine and examination of the kidneys shows that the tubules are plugged by blood pigment in the form of brownish granules and

mares; it is generally agreed that this condition is associated with an intravascular hemolysis of the donor's corpuscles due in nearly all cases to incompatibility between bloods of the donor and recipient. Blood grouping has greatly reduced though not entirely eliminated the chances of such incompatible transfusions.

In most cases in which the donor's and recipient's bloods have been re-examined after the occurrence of a hemolytic reaction they have been found to be incompatible. DeGowin and Baldridge (1934) however, report two cases of death with suppression of urine in which a re-test of the donor's and recipient's bloods showed no evidence of incompatibility. In one of these hemoglobinuria and the development of a definite jaundice left no doubt that intravascular hemolysis had occurred. Two cases out of seven reported by Goldring and Graef (1936) showed no evidence of incompatibility of the bloods on re-checking but presented undoubted evidence of hemolysis of the transfused corpuscles. In the first two of these cases citrated blood was used in the last two the transfusion was direct.

In cases where the transfusion is not direct one has to consider the possibility of some form of mishandling which would damage the red cells and either hemolyse them or render them liable to hemolysis in the recipient's circulation. Facey (1937) discussing reactions after blood transfusion stresses the possibility of faulty technique particularly in the case of inexperienced operators and mentions overheating as one of the errors. I have recently had sent to me sections of the kidney and an account of a case in which it appears probable that overheating was responsible for the hemolysis of the transfused blood.

A middle-aged woman was transfused for uterine hemorrhage. The donor was Group IV and his blood was matched against the recipient's and showed no incompatibility. 800 c.c. of citrated blood was used and this had been kept standing for nearly two hours in a receptacle with a water jacket the temperature of which was about 130° F. Within half an hour after transfusion catheterisation produced 25 c.c. of dark brown urine containing spherules of pigment and giving a strong Kastle-Meyer reaction for iron-containing hemoglobin derivatives. Spectroscopically it showed the bands of methemoglobin. The pigment gradually disappeared from the urine during the next two or three days but a nearly complete suppression of urine (2-3 oz. daily) had developed and the blood urea steadily rose reaching 540 mg. per 100 c.c. on the twelfth day after transfusion. The patient meanwhile became more drowsy with occasional vomiting but no jaundice and died on the fourteenth day after transfusion.

Post-mortem the kidneys (weighing 200 g. each) showed a deep purple red colour of the outer part of the cortex and a "very dark purple" medulla with streaks of deeper colour along the lines of the collecting tubules. The frozen section received proved not sufficiently good for fine details, but the most obvious lesion was a large amount of dark brown pigment in the lower convoluted and collecting tubules. The only other abnormality was oedema of the lower lobes of both lungs.

There seems no rational reason for heating blood for transfusion purposes above room temperature. As far as concerns the preservation of the blood this undergoes least change at low temperatures (5° C.). Blood kept outside the body at body heat (37° C.) deteriorates more rapidly than cool blood both as regards the condition of the red cells and as regards the various demonstrable antibodies in the plasma. As far as the cooling effect on the patient is concerned in rapid transfusion the blood is still warm from the donor and in slow transfusion unless special apparatus is used to heat the blood at a point close to the needle

it cools down to room temperature by the time it reaches the patient's vein. On making inquiries at Manchester Royal Infirmary I find that large numbers of slow transfusions have been given with complete success without any attempt to keep the blood warm. If for any reason it is necessary to keep the blood for any length of time before transfusing it is certainly undesirable to keep it warm during this period.

Cause of Suppression of Urine

Collections of brown granular pigment in the renal tubules are characteristic of suppression of urine following blood transfusion but they are also found in cases of intravascular hemolysis due to other causes particularly in blackwater fever where death from suppression of urine is not uncommon.

Yorke and Naus (1911) while investigating the pathogenesis of blackwater fever produced deposits of brown granular pigment in the renal tubules of rabbits by intravenous injections of solutions of hemoglobin. By this means they succeeded in producing suppression of urine in several animals, but found that this result could only be achieved if the animals were kept on a dry diet free from green food. Rabbits kept on an ordinary diet with green vegetables excreted the hemoglobin in an unchanged condition in the urine; no pigment was deposited in the tubules and no urinary suppression resulted. It appeared that the formation of the granular pigment in the renal tubules was related in some way to the condition of the urine, but the precise factors necessary for its deposition were first worked out by Baker and Dodds (1925).

We repeated and confirmed the findings of Yorke and Naus and further concluded that if hemoglobin is injected intravenously into rabbits it is excreted by the kidneys and reaches the renal tubules where one of two events may occur. (a) If the reaction of the urine be on the alkaline side of pH 6 the hemoglobin will be excreted unchanged and appear in the urine as oxyhemoglobin, the urine will be red and the kidney will take no harm. (b) If the reaction of the urine is as acid as pH 6 and if there is sufficient concentration of sodium chloride (over 1 per cent) the hemoglobin will be precipitated in the tubules as a brown granular pigment. The urine will then be brownish, will show a brown precipitate and will contain casts of the urinary tubules composed of similar brown granules massed together.

The kidneys of the rabbits secreting brown urine showed brown granular debris filling many of the renal tubules chiefly the collecting tubules. A certain proportion of these rabbits developed suppression of urine and became ill and showed an increase of blood urea (up to 300 mg. per 100 c.c.). Rabbits secreting the hemoglobin in an unchanged state as oxyhemoglobin never showed any evidence of renal damage.

On the strength of these animal and chemical studies and by the study of two human cases of suppression of urine following transfusion we concluded that the urinary suppression resulted from hemoglobinuria only when the urine was acid and we pointed out that the timely administration of alkali preferable intravenously should prevent this complication.

Both the cases we reported occurred unfortunately before we had worked out the problem and we have never had the opportunity of observing the effect of alkalinisation on a human subject. Since our paper was published in 1925 many cases of post transfusion suppression have been reported but in only very few of these can I find that alkalinisation has been

attempted and even in these it has obviously been tried much too late

Several writers on the subject have evidently failed to grasp the significance of our findings which have, unfortunately, not been generally applied to the prevention and treatment of this condition. Their significance has, however, been realised by two recent groups of workers, Goldring and Graef (1936) and DeGowin, Osterhagen, and Andersch (1937). The latter have repeated our experiments using dogs instead of rabbits and have confirmed the fact that animals secreting an alkaline urine suffer no renal damage while those secreting acid urine are liable to die from renal insufficiency produced by obstruction of the kidney tubules by pigment derived from hæmoglobin. They conclude their paper with the remark "These studies substantially confirm the experiments performed on rabbits by Baker and Dodds." It is satisfactory to find that our conclusions, based largely on studies of the rabbit, which normally secretes an alkaline urine, are equally applicable to the dog, which, like man, normally secretes acid urine.

ALTERNATIVE EXPLANATIONS

Before considering in more detail the mechanism of intrarenal obstruction it will be as well to discuss briefly some alternative explanations of the renal failure.

Bordley (1931) from a consideration of 17 cases, 14 of which were collected from the literature, concludes that there are four possible explanations of the renal damage:—

- (1) Mechanical blockage of the tubules by the granular debris
- (2) The kidneys are sensitive to certain bodies contained in the injected blood and the functional decline results from a local reaction which is of the nature of an anaphylactic shock
- (3) The immediate transfusion reaction brings about a metabolic disturbance that affects renal function
- (4) Damage to the renal tissue by toxic substances set free in the blood at the time of the transfusion

The last three of these possibilities cover a wide and indefinite field and the problem cannot profitably be discussed under these headings. It will be more to the point to consider first what part of the transfused blood is responsible for the renal damage.

(1) *Is it the plasma or the corpuscles?*—The answer to this is given by a case reported by DeGowin and Baldridge (1934) where hæmoglobinuria, jaundice, and a fatal suppression of urine followed transfusion with washed red corpuscles. This case and the experiments of Lorke and Nauss (1911) and Baker and Dodds (1925), in which suppression of urine in rabbits was produced by lysed washed red cells, prove definitely that the corpuscles are responsible for the damage.

(2) *What part of the corpuscles is responsible?*—The corpuscles can be separated into the hæmoglobin and the stroma and in our experiments on rabbits it was found necessary to remove the stroma by filtration in order to avoid capillary emboli and thrombosis in the lungs, which caused immediate death in these animals when whole lysed corpuscles were injected intravenously. In our experiments therefore urinary suppression and nitrogen retention was produced by the hæmoglobin fraction alone. We can say therefore that hæmoglobin liberated by intravascular hæmolysis of the transfused corpuscles is responsible for the renal damage.

(3) *Is hæmoglobin per se toxic to the kidneys or is the effect dependent from the formation of the granular*

precipitate in the tubules?—DeGowin and Baldridge (1934) quoting the experiments of Mason and Mann (1931) and Hesse and Filatov (1933) who showed that hæmoglobin had a vasoconstrictor effect on the kidney say "It is as yet not possible to say whether the vasoconstrictor effect or the blocking and destruction of tubular epithelium is the more important." It is clear that the idea that the suppression of urine is due to a vasoconstriction produced by hæmoglobin would not explain the fact that, in rabbits and dogs secreting an alkaline urine, hæmoglobin produces no signs of serious renal damage as judged by microscopic examination of the kidney and by the absence of nitrogen retention. Moreover of the 7 cases of post-transfusion suppression reported by Goldring and Graef (1936) 4 (Cases 2, 3, 5, and 7) developed a complete or partial suppression which lasted from seven to sixteen days, but was then followed by a diuresis and gradual recovery. Case 2 showed only a short period of hæmoglobinuria which had disappeared entirely by the fourth day following the transfusion, yet the non protein nitrogen of the blood continued to rise during a further seven days, after which diuresis set in and recovery took place. This would be a peculiarly persistent vasoconstrictor effect, especially in view of the fact that Mason and Mann describe the effect of hæmoglobin as "a definite, sharp, transient decrease in volume of the kidney." DeGowin, Osterhagen, and Andersch, in their (1937) paper quoted above, bring further evidence against the vasoconstriction hypothesis of Hesse and his co workers.

The outstanding fact which cannot be explained by any of the suggested alternatives but can be explained on our hypothesis is that under certain conditions a gross hæmoglobinuria may occur without any evidence of renal damage, whereas under other conditions the secretion of urine is suppressed.

Hæmoglobinuria without appreciable failure in renal function occurs in man in (1) paroxysmal hæmoglobinuria, (2) in blackwater fever, particularly in those cases treated with alkalis, and (3) after the experimental injections of hæmoglobin carried out by Sellards and Minot (1916). In animals Baylis (1920) found that injection hæmolyzed blood was innocuous to the cat and dog, and as already stated, rabbits with normally alkaline urine are not adversely affected by transfusion with filtered hæmoglobin solutions. On the other hand, we have the cases of post transfusion and blackwater fever suppression in man and the experimentally produced suppression in rabbits and in dogs secreting an acid urine.

THE AUTHOR'S VIEW

The following summarises what I believe to be the correct explanation of these apparently contradictory findings.

The urine is excreted from the glomeruli as a dilute transudate the reaction of which is in the region of that of the blood plasma. During its passage through the renal tubules it becomes more concentrated either by absorption of water or by the addition of salts. In hæmoglobinuria the hæmoglobin must either pass out in the glomerular transudate or it must be excreted by the tubules, in either case it will arrive in the lower convoluted tubules where the urine is becoming more concentrated. If the concentrated urine is sufficiently acid and has a sufficient salt content the hæmoglobin undergoes a change, first to methæmoglobin and then to hæmatin the latter forming a brown granular precipitate in the renal tubules. If the urine does not become sufficiently acid and

concentrated the hæmoglobin undergoes no change but is excreted in solution as oxyhæmoglobin in this event the kidney suffers no ill effects.

With a concentrated urine which precipitates the hæmoglobin there are three possibilities depending on the amount of hæmoglobin excreted and on the degree of concentration of the urine.

(1) With a considerable hæmoglobin excretion and a very concentrated urine there is a massive precipitate of hæmatin in the renal tubules. This packs down into masses which cause permanent blockage and death from complete or nearly complete suppression of urine.

(2) With either a small amount of hæmoglobin or a rather less concentrated urine the precipitate is less copious and produces a similar but less massive obstruction. With the gradual extrusion of the hæmatin casts, possibly encouraged by a diuresis produced by the raised blood urea the obstruction is relieved and the patient recovers.

(3) With still less hæmoglobin or only a moderately concentrated urine a light precipitate of hæmatin forms in the renal tubules. This is easily passed out and appears in the urine as lightly packed granular casts which are associated with a fair amount of brown granular precipitate formed in the bladder. No urinary suppression or gross functional damage to the kidney results in these circumstances. This condition was evidently present in the case of paroxysmal hæmoglobinuria whose urine we had the opportunity of examining (Baker and Dodds, 1926).

Recovery from Intrarenal Obstruction

In a series of 17 cases of post-transfusion suppression reported by Bordley (1931) there were 5 recoveries and in a recent series of 7 reported by Goldring and Graef (1936) 4 recovered. The mechanism of this recovery presents an interesting problem.

The sequence of events is usually as follows. After a period of partial suppression and steadily rising azotæmia with uræmic symptoms, lasting from seven to sixteen days the excretion of urine begins to improve and in the course of four to six days mounts steadily from an almost complete suppression to an output of 3-4 litres a day. With the establishment of this diuresis there starts a steady fall in the non-protein nitrogen of the blood and the patient makes a rapid recovery. Recovery may take place after a high grade of azotæmia has been reached. In Case 5 of the series reported by Goldring and Graef recovery occurred after sixteen days partial suppression with an azotæmia reaching 520 mg non-protein nitrogen per 100 c.c.m. The prolonged obstruction produced no permanent impairment of renal function in this case.

We noted a very similar recovery of renal function in our experiments on rabbits and made the following remark (Baker and Dodds 1925 p. 254).

When the urine is made acid it is not an easy matter permanently to obstruct the kidney of a rabbit by injections of hæmoglobin. Such an animal may recover after several 20 c.c. injections of strong hæmoglobin solution. There is no doubt that such injections lead to a temporary blockage of the renal tubules. It can be shown however that the kidney is capable of recovering its function after such an obstruction.

At the time of these experiments we were not aware that a similar process of recovery could take place in man and were surprised at the powers of recovery of our rabbits.

The evidence that recovery is dependent on the extrusion of the hæmatin casts from the renal tubules is based on the examination of the urine of rabbits recovering from obstruction. Our remarks on this were as follows—

"When obstruction has occurred in a rabbit with an acid urine an examination of samples of urine passed during the period of recovery shows numerous darkly coloured

compact casts which form a slight sediment in an otherwise perfectly clear urine. These casts undoubtedly correspond to the more compact masses of debris which are seen in sections blocking the straight tubules. Their extrusion no doubt frees the kidney to a considerable extent.

I have never had the opportunity of examining the urine of a patient who recovered from post-transfusion suppression, nor does there appear to be any record of studies of the urinary deposit in such a case.

Nature of Granular Precipitate in Renal Tubules

A detailed chemical study of the precipitate in the renal tubules and in the urine has as far as I am aware, never been made. It would obviously be very difficult to investigate in any detail the pigment in the tubules. It has however been shown that it gives a positive benzidine reaction (Goldring and Graef 1936) and that it does not give the Prussian blue reaction for inorganic iron. This proves that it is either hæmoglobin or one of its degradation products containing organically combined iron. Its brown colour and granular form tells us that it is not unchanged hæmoglobin. As regards the pigment in the urine part of which is derived from casts extruded from the kidney this consists of at least two substances for if the urine is allowed to settle the supernatant fluid gives the spectrum of methæmoglobin while the granular precipitate gives the reactions for hæmatin (Baker and Dodds 1925 p. 258). Hæmatin like the pigment in the renal tubules, gives the benzidine but not the Prussian blue reaction. These two pigments (methæmoglobin and hæmatin) were produced *in vitro* by adding hæmoglobin to acid urine.

The exact chemical composition of the precipitate is however of purely academic interest; what is of practical importance is the mechanism of its formation and this is set forth in detail in our paper. An important point which explains the different grades of renal obstruction (ranging from complete to nil) is the variation in the amount of precipitation with changes in the pH and salt content of the urine. With a very concentrated urine the precipitation is complete and relatively rapid and little if any methæmoglobin remains in solution; with less concentration its precipitation is slower and partial. With a fairly rapid and complete precipitation which would only occur with a very concentrated urine it is quite possible that no soluble pigment would escape from the kidney even though some urine was excreted. This probably explains the exceptional cases where hæmoglobinuria was definitely stated to be absent, although pigment was found in the renal tubules post mortem. Pigment casts would almost certainly have been found in the urine in these cases had they been looked for.

Although hæmolytic jaundice usually occurs it is not always present. Its absence even in carefully recorded cases cannot be taken to negative an intravascular hæmolytic process. This point is illustrated by the very well recorded series of 7 cases collected by Goldring and Graef (1936). All these showed hæmoglobinuria and all developed jaundice except Case 7 but there must have been hæmoglobinuria in this case to produce the hæmoglobinuria. If hæmoglobinuria without jaundice was also present in the case I report in this paper.

Changes in the Kidneys

The naked-eye appearance of the kidneys is variable and not very distinctive. They are usually enlarged

sometimes weighing up to about 8 oz each, the cortex is usually swollen and may show the pale opaque appearance of marked albuminous degeneration or, on the other hand, it may be congested. The medulla shows a dark red brown striated appearance produced in part by congestion of the vasa recta and in part by deposits of brown pigment in the medullary tubules. Microscopically the characteristic change is a deposit of granular brown pigment in the tubules, this is most obvious in the collecting tubules, but may in some cases extend as high as the second convoluted tubules (as in our Case 1, Baker and Dodds 1925). This pigment is in the form of granules of size varying from that of a micrococcus up to globules and masses considerably larger than red blood cells. In unstained sections it is brown in colour, but it appears red or brownish red with eosin staining and, as noted above, it gives a benzidine but not a Prussian blue reaction. The pigment is mixed with a variable amount of cell debris mainly derived from the tubular epithelium and tends to form compact casts in the lower parts of the tubular systems.

The other changes in the kidneys consist of (a) albuminous degeneration of the tubular epithelium, and (b) dilatation of the tubules and of Bowman's capsules. Oedema and infiltration of the interstitial tissues with chronic inflammatory cells have been described in several cases. The enlargement of the kidneys appears to be produced by albuminous degeneration and dilatation of the tubules and possibly to some extent by oedema and cellular infiltration of the interstitial tissues. The albuminous degeneration may be marked but there is no tubular necrosis nor are appreciable fatty changes present. The amount of dilatation of the tubules and of Bowman's capsules is very variable and possibly depends on the extent of the precipitate within them (and the point at which obstruction occurs). In our first case where the pigment precipitate extended as high as the second convoluted tubules there was a general dilatation of all the tubules and of Bowman's capsules, and I have sections of a kidney from a case of blackwater fever with urinary suppression which shows an almost identical condition. In Witts's case (1929), in which a detailed description of the microscopic appearances of the kidneys was given by Turnbull all the tubules were dilated, but the capsule of Bowman was "usually only slightly dilated". The deposit of pigment did not extend as high as the convoluted tubules in this case. In our second case there was no obvious dilatation of the tubules or of Bowman's capsules and the pigment was confined to the lower part of the tubular system.

Interstitial oedema and perivascular and inter tubular infiltration with chronic inflammatory cells, which were noted in Witts's case and in several others, if directly related to the renal obstruction, appear to be late results, neither of these features were present in our first case which died early on the fourth day following transfusion.

We may therefore summarise the more important microscopic findings as follows—

- (1) A precipitate of haematin in the lower parts of the tubular systems extending in some cases, into the second convoluted tubules.
- (2) Albuminous degeneration of the tubular epithelium without necrotic or fatty changes but with desquamation of some of the cells into the tubular lumina.
- (3) A variable degree of general dilatation of the tubular systems which may be marked and may also involve Bowman's capsules.

(4) No signs of inflammatory or other significant lesions in the glomeruli.

(5) As a late result a varying amount of oedema and, possibly, chronic inflammatory infiltration of the perivascular and intertubular connective tissues.

Prevention and Treatment of Post-transfusion Suppression

Since haemoglobin is precipitated only when the urine is acid intrarenal obstruction will not occur in a patient whose urine is neutral or alkaline during the period of haemoglobinuria following an incompatible blood transfusion. If, however, a precipitate has formed in the renal tubules in a patient with an acid urine it is doubtful whether alkalinisation will effect a cure. Precipitates of haematin are not very soluble in alkaline urine (pH 7.5) but they are more soluble in this than in acid urine. When the precipitate is sufficiently massive to produce complete suppression one can, presumably, expect little from alkalinisation, but in most cases the suppression is not complete and an alkaline urine should help by dissolving some of the precipitate in the tubules. Since, as we have seen, a fair proportion of cases have recovered from the obstruction spontaneously, probably by the extrusion of the obstructing casts, a relatively slight solution of some of the pigment may well turn the scale in favour of recovery. Early recognition and prompt treatment of the condition by alkalinisation appears to offer the best prospect of recovery. The treatment of blackwater fever by alkalis has been practised for many years.

Cases must occur in which an incompatible transfusion results in haemoglobinuria, but, because the patient's urine is not very acid, there is no suppression of urine. I have heard of one such case, but the majority have evidently not been considered worth recording.

SUMMARY

1 A case is described in which urinary suppression followed transfusion with overheated blood.

2 The mechanism of post transfusion suppression is discussed in the light of older and more recent work and it is concluded that the view put forward by Baker and Dodds (1925) furnishes the only adequate explanation of the observed facts.

3 According to this view the urinary suppression results from an intrarenal obstruction due to excretion of haemoglobin with a urine of high acidity and salt concentration. Under these conditions the excreted haemoglobin is converted into a granular deposit of haematin which obstructs the renal tubules. Haemoglobin per se is innocuous to the kidney.

4 The prevention and treatment of the condition is briefly considered.

HOSPITAL'S CHANGE OF NAME.—The City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, has been renamed the London Chest Hospital.

TRANSPLANTATION OF THE CORNEA FROM PRESERVED CADAVERS' EYES

By V. P. FILATOV M.D.

OF ODESSA, U.S.S.R.

TILL recently the chief source of material for the transplantation of the cornea in man consisted of eyes enucleated from living people owing to some disease of the eye or of the orbit. The possibility of obtaining a permanent transparent union of the corneal graft from the living eye has been proved beyond any doubt many cases have been recorded where the transparency of the cornea has been observed for nine months or more—notably 31 cases from Eieschnig's clinic (Ascher 1919 1922 Liebesch 1930 Stanka 1927) 16 from my own observation (Filatov 1935b) and the cases of Zirm (1907) Plange (1912) Löhlein (1912) Tudor Thomas (1933 1934) Castroviejo (1933 1934 1935) Vasutinsky (1935) Belajev (1924) and other authors. About 70 cases are on record of successful transplantation of the cornea from living eyes. Almost all of these successes have been obtained with the method of partial penetrating transplantation in a few of the cases the lamellar partial transplantation was made while one only fairly successful case has been recorded (Schumanovsky 1913) of complete transplantation.

All my cases were under observation for not less than a year the only exception being a patient who died seven and a half months after the operation. As regards more remote results of transplantation from the living eye a number of cases have been recorded by Eieschnig as well as by myself which have been under observation for several years. Fig. 1 shows eyes whose transplants were found to be transparent after varying periods.

GRAFTS FROM THE LIVING

CASE A—Complete leukaemia, developed after recurring scrofulous keratitis. In the leukaemia some remnants of the semi-transparent corneal tissue. Vision before operation (Oct 18th, 1923) was equivalent to perception of light vision after operation was 3/80 on aphakic correction. This vision remained unchanged till the patient died 6 years later (Filatov 1923).

CASE B—Dense opacity after parenchymatous keratitis. Vision before operation (Dec 23rd 1930) 0-025. The transplant retained a fine transparency during the time of observation (5½ years). Vision after the operation was 0.7 till May 1934 when it became and remained 0.4. Fundus oculi clearly visible (Filatov and Velter 1934) (Fig. 1).

CASE C—Dense opacity of the central part of the cornea of the right eye and less dense opacity on its periphery both developed after parenchymatous keratitis. Vision before the operation (Feb 2nd 1932) was 3/60. The transplant is now 4 years and 7 months after the operation still fully transparent. Vision was 0.5 (Filatov and Velter 1934) (Fig. 1).

CASE D—Opacity developed in the left eye after parenchymatous keratitis. Vision before the operation (March 10th 1932) was 5/60. The transplant is now 4½ years after the operation fully transparent. Vision=0.3 (Filatov and Velter 1934).

CASE E—Leukaemia developed after a traumatic ulcer. In the upper third of the cornea a strip of the tissue is transparent. Vision before the operation 1/80; after the operation performed in December 1931 by Prof. Zykulenko vision rose to 0.4. Binocular vision was restored. Length of observation time 4 years 9 months (Zykulenko and Velter 1933) (Fig. 1).

These results illustrate the bright prospects of corneal grafting and there is now reason to think that the operation may prove to be a practical means of overcoming the blindness and disablement due to leukaemia.

NEED FOR NEW SOURCES

The question now arose whether the number of suitable eyes removed from living people would be enough for all the cases in which the transplantation was indicated. For it must be kept in mind that there are six million blind in the world and fifteen millions suffering from diseases of the eye (Samoulov and Braunstein 1936). According to the official census in 1928 there were 234 800 blind people in the Soviet Union (Savvatov 1932). In at least 43 per cent. of this number blindness is due to leukaemia for to this cause may be put down all cases of blindness from trachoma (20-64 per cent.) from small pox (10-63 per cent.) from diseases of the cornea (8-43 per cent.) and from blennorrhoea of the newly born (3-45 per cent.) it is also necessary to add some cases of blindness due to trauma. Of this number—about a hundred thousand—a great many cases are not fit for the operation of corneal transplantation owing to various complications, such as glaucoma atrophy of the eye staphylocoma symblepharon and persisting trachoma. Yet the number of cases in which the operation is indicated still amounts to many thousands. The number of candidates for corneal transplantation would be increased even more by those who though afflicted with leukaemia in both eyes, have not been registered as being blind because their vision is above 1/200. Such cases lend themselves particularly well to the operation of corneal transplantation for these leukaemata contain remnants of corneal tissue. Furthermore, since the transplantation of the cornea successfully competes with iridectomy the number of candidates for the operation may indeed be enormous.

In view of the great success already achieved in the work with corneal transplantation it seemed high time to attempt to find a new source of transparent corneas. If the serious difficulty of supply was to be overcome. It was only natural for me first of all to turn my attention to the dead body. For some time cadavers eyes from adults as well as from foetuses, had been employed in a few single cases by several surgeons. Some used corneas immediately or during the first hours after death (Fuchs 1901 Schumanovsky 1913, Magitot 1912 Savellier 1927). Other surgeons removed the eyes from the stillborn 10-36 hours after death. Only in the case reported by Magitot (1912) however was a permanently transparent union of the transplant established by fairly long observation. These data were of course far too meagre and the use of cadavers material on a large scale as a substitute for living material, to meet the demands for transplantation had not previously been considered by anybody.

This then was the state of affairs when I studied the problem in 1931. Its solution I based on the remarkable case reported by Morax and Magitot (1912) who obtained a permanently transparent union of the cornea removed from a living person and preserved in the donor's blood at a temperature of minus 6 C for eight days.

METHOD

From the very beginning of my investigation on the feasibility of transplanting cadaver cornea I employed corneas taken from cadaver eyes preserved for many hours before the operation at a relatively

low temperature The eyes were obtained (1) from bodies of those who had not died from infectious diseases nor malignant tumours—syphilis was excluded by serological tests before or after death and sometimes also by autopsy, (2) after death from accidents or suicide, brought into the medico judicial morgue—syphilis was excluded by serological tests, and the absence of acute infections by the anamnesis and sometimes by autopsy

The enucleated eyes were in some cases placed in a sterile jar with a tight fitting stopper, cornea upwards, sometimes the jar was filled with the donors fresh clotted blood while in still other cases the blood was citrated The jars were kept in an ice chest at 4° – 6° C On the day of operation the jar containing the eye, surrounded by ice, was brought into the operation room, where it remained for about an hour before the cornea was excised and transplanted The corneas of eyes preserved in this manner usually appeared to be somewhat dimmed, the epithelium being slightly stippled The eyes were kept for periods varying from 10–56 hours, while in one case it was six days Before excising the transplant the cornea was washed with a fresh aqueous solution, brilliant green (1 1000)

RESULTS

From 1932 till January, 1936, I have performed 95 operations of the partial penetrating transplantation of corneas prepared in this way (Filatov 1934, 1935a) In nearly all of these cases I used my own operative technique

I employed either an FM 1 or an FM 3 trephine and covered the transplant with a flap of conjunctiva (Filatov 1934a and b, 1935b and c)

tissue film had formed on the posterior surface of the transplant, must not be referred to the total number of eyes operated on, but only to 49 of them, since in 46 eyes the leukomata were greatly complicated by glaucoma, buphthalmos, apphation, subatroph of the eye, &c, in such eyes there is no hope at all of obtaining a transparent union While the operation is performed in the last resort as a concession to the supplications of the patients, it is necessary to keep separate records for such eyes

Out of the 18 operations in which transparent union was recorded, 14 cases have been under observa-

FIG 1—Corneal grafts from the living

tion for over nine months, the remaining 4 cases having been followed up for a shorter time Some of these 18 cases of transparent union are summarised below and illustrated by untouched photographs—

CASE 1*—Leukoma due to scrofulous keratitis Vision before operation perception of hand movements Transplantation of cadaver's cornea on March 17th, 1935 The eye had been taken from the cadaver 12 hours after death and subsequently preserved for a further 25 hours at 4° – 6° C

Result—Vision = 3/60, on eccentric fixation (amblyopia) Fundus oculi clearly visible Length of observation (Oct 1st, 1936) 1½ years (Fig 2)

CASE 2*—Leukoma developed after an ulcer Vision perception of hand movements Transplantation of

FIG 2—Corneal grafts from cadavers The eyelids are retracted to display the cornea

There was not a single case of necrosis of the transplant The post operative course was pretty much the same as in transplantation from living eyes

The following were the results of the 95 operations

There were 46 cases of non transparent union and 17 cases of half transparent union In one of these cases a greyish film has formed on the posterior surface of the transplant

In 4 cases, in one of which the transplantation was performed after six days' preservation of the eye, the union was transparent but a connective tissue film had formed in each case on the posterior surface of the transplant

Lastly there were 18 cases of transparent union By this I mean that the details of the anterior chamber could be clearly made out at least through a part of the transplant or that there was a good light reflex through it

The 18 cases of transparent union and also those cases of transparent union in which a connective

cadaver's cornea on Dec 12th 1935 The eye taken from the cadaver had been preserved for 27 hours

Result—Vision = 0.4 Fundus oculi clearly visible Anterior pole cataract distinctly visible Length of observation (Nov 1st, 1936) 10½ months (Fig 2)

CASE 3—Leukoma formed after a thermic burn Vision before the operation perception of hand movements Transplantation of cadaver's cornea on Oct 28th, 1934 The eye had been removed from the cadaver 3 hours after death and subsequently preserved for 27 hours

Result—Vision = 0.4 Anterior pole cataract Fundus oculi clearly visible Length of observation (Nov 1st, 1936) 2 years (Fig 2)

CASE 4—Aged 12 Leukoma after parenchymatous keratitis Vision before the operation able to count fingers held before her face The eye had been taken from a cadaver 12 hours after death and subsequently preserved for 26 hours

* Cases 1, 2 and 5 were demonstrated at the All Union Meeting of Ophthalmologists of the U.S.S.R. in June, 1936

Result—Vision = 0.1 with a -0 D lens. Fundus oculi distinctly visible. Period of observation (Oct 1st 1936) 2½ years (Fig 2).

CASE 5—Leukoma after parenchymatous keratitis. Vision before the operation = 0.02. Transplantation of cadaver's cornea on Oct 28th 1936. Eye removed from the cadaver 2 hours after death preserved a further 28 hours.

Result—Vision = 0.0. Length of observation (Nov 1st 1936) 1½ months.

The cases cited above bear witness to the fact that a cornea from a cadaver's eye preserved at a temperature of 4–6 C is perfectly suitable for transplantation. Analysing my material and taking into account the quality of the leukomatous substratum in which the transplant from the cadaver is placed I have gained the impression that the results of transplantation from cadaver's eyes are not inferior to those obtained with grafts from living eyes. For a final opinion it is of course still necessary to follow up the more remote results of the operations. On the other hand it may be said that the present results in my series of cases that have been under observation from 1½ to 2½ years, would already seem to justify the expectation that the more remote results will be favourable.

Investigations are being made in my laboratory on the retention of vitality by the cornea under various conditions of preservation. Experiments carried on by Dr Bashenova have shown that the cornea of rabbits' eyes may show a good tissue growth when planted in vitro even after ten days' preservation at a temperature of 2 C. In collaboration with Bashenova I have obtained a tissue culture from dried cornea. Working in my laboratory Velter has shown in rabbits the possibility of transparent union of the cornea taken from eyes preserved at a temperature of +2 C. for as long as fifteen days. My pupil Dr Popenko has brought forth evidence for migration of cells and their formation into clusters in the cornea (and in other tissues) after preservation of the material for eight days at a temperature of 2 C.

CONCLUSIONS

The cornea from eyes of human cadavers, removed some hours after death and preserved at a temperature of 4–6 C is suitable for homoplastic transplantation in man the transplant retaining permanent transparency after union with the substratum.

The new source of material for transplantation opens up great possibilities for further investigations on corneal grafting.

In connexion with the transfusion of preserved cadavers' blood first applied to dogs by Prof W N Shamov and to man by Prof. Yudin the successful transplantation of preserved cadavers' cornea is of great interest not only from a clinical but also from a general biological point of view.

EFFECT OF CALCIUM AND VITAMINS A AND D ON INCIDENCE OF PREGNANCY TOXAEMIA

By G W THEOBALD M.D. Camb. M.R.C.P. Lond.
F.R.C.S. Edin. F.C.O.G.

THE following experiment, carried out at St Mary Abbots Hospital,* London during 1936 was devised to determine whether the mere addition of calcium and vitamins A and D to the diet of patients attending the antenatal clinic would have any effect on the incidence of toxæmic symptoms.

Apparently healthy women not more than twenty four weeks pregnant were divided by the sister into two groups when they first attended at the clinic, no attention being paid to their previous obstetric histories. They were divided at random in the following manner—

An equal number of blue and white beads were placed in a box. Each woman accepted for the experiment was asked to draw a bead from the box. Those who drew blue beads were placed in Group A while those who drew white beads were placed in Group B. The beads drawn out were placed in a separate container.

The patients in Group A were requested to take daily, for the remainder of their pregnancies, calcium lactate 20 grains, vitamin A (11 000 international units) and naturally occurring vitamin D (450 units); while those in Group B served as controls. The oil containing the vitamins was supplied in capsules of which four were to be taken every day while the calcium lactate was distributed in the form of tablets. No advice concerning diet was given to either group of patients.
